The genetic system, at one time thought to be immutable, is known to be subject to mutation. The mutation mechanism is molecular. Consider the DNA molecules in a cell. As we know, these molecules can replicate. Now, during the replication process accidents ("mistakes") of two kinds can occur: (*a*) the daughter molecular strings may differ from the parent string in the order or sequence of the nucleotides (i.e. the daughter DNA molecules are isomers of their parents), or (*b*) one or more nucleotides may be either deleted or inserted (substitution). And, because DNA controls protein synthesis, such "mistakes" are likely to ensue in the synthesis of proteins of kinds different from those contained in the parental cells(s) – i.e. the mutant DNA can "code for" (control the synthesis of) new proteins. And the latter make it possible for the offspring to interact in new – not necessarily more efficient – ways with its environment. The end result is a mutant organism – one that may or may not be viable. See Figure 3.5.

Mutations are not frequent but they are bound to occur either in large populations or along many generations. And the number of possible mutations, hence of possible new proteins, and therefore of possible organisms more or less different from their ancestors, is staggering. (Speak of the poor "possible worlds" imagined by philosophical logicians!) Mutation is indeed an inexhaustible source of biotic novelty. And because mutation occurs by chance and irrespective of its value or disvalue to the organisms, chance has been said to be the sole source of newness in the biosphere (Monod, 1970, p. 127). But this is an exaggeration. The chemical affinities at the root of the nucleotide sequence are hardly chancy, and the selective action of the environment has causal components as well as random ones. (See Sec. 3.)

The large number of possible mutations explains the proteinic uniqueness of each organism. Equivalently: it accounts for many individual differences within any given species – or what is misleadingly called "indi-

vidual variability". It also explains the large number of biospecies. And the limited environmental resources, with the accompanying competition for them, explains why biopopulations do not grow exponentially (except for limited periods). Finally, changes in environmental conditions – particularly important changes such as glaciations and continental drifts – explain why (*a*) most biospecies that have been on Earth have become extinct, and (*b*) the number of species can jump up or down during certain brief periods. (One such revolutionary period was the beginning of the Cambrian, when many species of multicellular organisms emerged.)

In view of the fashionable claim that whatever an organism is and does is programmed in its genome, it may be helpful to insist that what is inherited is a bit of genetic material carrying certain potentialities. These potentialities may or may not be actualized in the course of the organisms' life, according to the possibilities offered by the environment. (For the concepts of potentiality and actuality see Vol. 3, Ch. 4.) We may as well be more precise and adopt

DEFINITION 3.12 If b is an organism, then

(i) the *genome* of b = the potentiality of b at birth;

(ii) the *phenome* of b = the set of molar (global) properties of b in adult state.

While geneticists focus on the genome, others focus on the phenome. Both visions are myopic, for only a suitable genetic equipment allows the organism to cope with its environment, and only a suitable environment enables the genetic traits to "express" themselves (i.e. to become activated). Thus, while every organism inherits its genome, it evolves its own phenome in a given environment; the phenome depends then upon both the genome and the environment. Given the variability of both, evolution should come as no surprise. But evolution will concern us in Sec. 3, after we look at the philosophical background of the contemporary doctrines on development and heredity.

2.6. *Development, Heredity, and the Metaphysical Tradition*

Contemporary studies of development and heredity have been influenced, mostly unwittingly, by ancient metaphysical ideas on the relations between substance and property, on the one hand, and between potency and actuality on the other. In turn, the results of such studies should be allowed to influence our general ideas on the substance-property and the potency-actuality pairs.

Consider first the organ-function relation as a particular case of the substance-property relation. Every biofunction is the function of some organelle or some organ, but the converse is false: i.e. there may be organs that have no biofunction (the vestigial or "fossil" organs), and others that perform specific functions only at certain stages of development. In the latter case the organ sometimes precedes the functioning organ – or, as the misleading idiom has it, "organ precedes function". For example the eye, the reproductive system, and large parts of the brain of a cat are formed before they function fully.

The temporal precedence of the nonfunctional organ over the fully functional one would seem to refute the Platonic doctrine that form (or essence or idea) precedes existence. Not so, for the Platonist could rejoin that the form (function) is inserted into the organ when needed. What does refute the Platonic doctrine of forms is the well confirmed generalization that there is no form (function) without organ and, in general, no property without substance. (Cf. Vol. 3, Ch.2, Sec. 5.2.) The controversy between the substantialists ("organ determines function") and the functionalists ("function determines organ") is a particular case of the age-old metaphysical controversy over substance and property. This controversy dissolves upon realizing that neither determines the other. All that happens in the case of organs that do not perform their specific function during the entire life of an organism, is that their nonfunctional states precede in time the functional ones.

A second point where developmental biology and the theory of heredity make contact with metaphysics is over the question of preformation *vs.* emergence. There have been two classes of solution to the problem of explaining the development of an organism from egg through adulthood to final breakdown. One is to assume that all of the properties and patterns that appear in the course of development are just the unpacking or unfolding (*development*) of what was contained in potency (*preformed*) in the egg. Or, to put it into modern parlance, the assumption is that the genome contains a full set of "instructions" steering the organism through the successive stages of its development. This is the *preformationist* hypothesis held by Aristotle and Leibniz, and resurrected by some contemporary scientists who believe that biology is fully reducible to molecular biology. Preformationism denies real novelty, in particular the emergence of new properties that accompanies self-organization (Ch. 1, Sec. 3.2); and it minimizes or even ignores the role of the environment.

The partisans of *epigenesis* hold, on the contrary, that development is an epigenetic or creative process in which novelty occurs at every stage. They maintain that the organism starts at a low state of organization and acquires new components and properties, as well as loses others as it develops. Epigeneticism is of course the hypothesis underlying all of classical embryology as well as the contemporary studies on the origin of life.

The molecular biology revolution has all but eclipsed epigeneticism. What is fashionable nowadays is genetic preformationism. Yet fashion need not concide with truth. The claim that development is just the deployment or implementation of a blueprint contained in the genome is no more illuminating or correct than holding that it is guided by an immaterial *élan vital* (Bergson, 1907) – or that it consists ultimately in the embodiment of Platonic self-existing geometric shapes (Thom, 1972). Surely development can be neither purely preformative nor purely epigenetic, if only because the environment supplies the raw materials for it and weeds out the maladapted organisms, as well as offers chances to the preadapted ones.

It seems that each view, either preformationism or epigeneticism, has alternatively accelerated and blocked the development of biology. Preformationism may have stimulated the purely descriptive phase of embryology and the beginnings of molecular biology, whereas epigeneticism may have stimulated experimental embryology (particularly investigations into the mechanisms of morphogenesis) and ecology. But neither view explains anything because each is just a programmatic hypothesis or a framework for discussing development and heredity. Indeed, far from being full-fledged theories, preformationism and epigeneticism are ontological hypotheses summarizing entire bodies of ideas, where sound data and conjectures are inextricably mixed up with metaphysical fossils.

It seems quite possible that the next breakthrough in the fields of development and heredity will come from a sort of merger of the two frameworks, one harmonizing two lines of research: (*a*) the search for specific development mechanisms (e.g. the mechanical constraints each cell is subjected to, the synthesis and action of morphogenes, and the interactions with the nutrient medium), and (*b*) the genetic "programming" of development possibilities – potentialities that are "encoded" in the genome in the sense that the latter contains, not "instructions", but some of the key reactants and templates required for the occurrence of certain biochemical reactions. But let us not attempt to write the history of the future.

3. EVOLUTION

3.1. *Adaptation*

A salient feature of our biosphere is its rich variety. There are at least three million biospecies (Dobzhansky, 1970), and no two strictly identical individuals in any of them. (Even so-called identical twins are somewhat different.) This variety is a result of four billion years of evolution. And the evolutionary process is in turn the net effect of a combination of genic changes (mutations and recombinations) with environmental selection. The process seems to be continuing: there is no reason to believe that it stopped the moment man became aware of it. In fact the extinction of a number of species has been certified during our own lifetime, and it is likely that new species are forming right now. In short, bioevolution is revolutionary – or creative (Bergson, 1907), or emergent (Lloyd Morgan, 1933).

Anthropomorphically speaking, evolution is a trial and error, or success and failure, story. Success is called *adaptation*, and failure *maladaptation*. A biopopulation of well adapted individuals thrives or expands, whereas one of maladapted individuals declines. This looks obvious but ceases to be so as soon as one stops and examines the very term 'adaptation': he then realizes how tricky it is (Williams, 1966). In fact, the word 'adaptation' is ambiguous, as it designates at least three different concepts, namely the following:

A_1 = *suitability* of a subsystem (organelle, organ, etc.) to a function, or high biovalue of the subsystem for the entire organism;

A_2 = *adjustment* of the organism to its environment;

A_3 = *fertility* of a biopopulation.

That these are indeed different concepts, is realized upon displaying their structure. A_1 is a relation between subsystems and organisms, A_2 a relation between organisms and environments, and A_3 an intrinsic property of organisms. A methodological examination confirms the difference. In fact the way to find out whether something has the property A_1 is to conduct certain biochemical or physiological experiments or observations in a constant environment. By varying environmental factors we can ascertain whether an organism possesses property A_2. And the criterion for A_3 is the count of offspring.

In sum, we must be reconciled with the fact that 'adaptation' is an ambiguous term. This seems obvious, yet it is overlooked by those who claim that only population genetics uses "the correct" concept, namely A_3. And it is equally overlooked by those who claim that the Darwin–Spencer principle of the *survival of the fittest* is tautological. Indeed, survivorship or fertility (A_3) is not the same as fitness or adjustment (A_2) but an indicator of the latter. The logical relations among the three concepts are these: $A_3 \Rightarrow A_2 \Rightarrow A_1$, i.e. subsystem biovalue is necessary for adjustment, which is in turn necessary for fertility.

It goes without saying that adaptation of any kind is time-dependent. I.e., A_1, A_2 and A_3 vary in time, either because of internal changes, or environmental changes, or both. The case of sudden environmental changes is particularly interesting, for they are bound to favor some biopopulations while hurting others. In the first case one speaks of *preadaptation*, in the second of *premaladaptation*. In keeping with the above distinction among three adaptation concepts, we distinguish three preadaptation types:

PA_1 switch of function(s) to other(s) of greater biovalue;

PA_2 improved adjustment to the environment;

PA_3 greater fertility.

As with the case of adaptation, the first is necessary for the second, which is in turn necessary for the third, i.e. $PA_3 \Rightarrow PA_2 \Rightarrow PA_1$.

Neither of the three kinds of adaptation or preadaptation calls for teleological considerations. The adapted or preadapted organisms may survive and reproduce, the maladapted ones don't, and that is the end of the story. To invoke adaptive *plans* at all evolutionary stages (Holland, 1975) is to indulge in anthropomorphism. There is not a shred of evidence for such master plans except in the case of man, and no serious biological theory involves them. Instead of imagining adaptive plans we should hypothesize and check adaptation mechanisms.

3.2. *Adaptation Mechanism*

Random mutation and recombination give rise to a great variety of unequally adapted organisms. The environment selects the best adapted amongst them and thus steers evolutionary change. Hence the environment is just as creative as the genetic material. But, whereas the latter varies randomly, the environment exerts a directional action. (Directional, not goal-directed – i.e. changing in a given direction but not directed towards a goal, let alone by a goal.) That, in a nutshell, is what the modern theory of evolution is all about.

A classical experiment confirming this theory is the following (Waddington, 1959). Larvae of fruit flies (*Drosophila*) are exposed to diverse environmental changes, such as excess salt, or heat, or ether vapour. If fed salted food, many of the flies die. The survivors happen to exhibit an enlargement of certain papillae conjectured to be involved in the regulation of salt concentration in the body. (The hypothesis is that this is a preadaptation, i.e. that those individuals that happen to be born with the more efficient salt controls, i.e. which are preadapted to the new circumstances, survive.) The 20th generation is definitely more resistant to salted food than the unselected or control group: roughly twice as many selected flies survive when given food with 5 percent salt added. The new character, i.e. the ability to cope with abnormally high salt concentrations, does not appear at one stroke but is instead the result of a gradual accumulation brought about by genic changes in conjunction with environmental pressures.

No master plan guides the gradual adaptation of organisms to their environment – until the latter changes unfavorably and maladaptation sets in, and eventually the population is decimated or even wiped out. Indeed, adaptation can be explained as the outcome of a random process powered by genic variation (mutation or recombination) and guided by the environment. To clarify this point consider a single property P, such as the size of the salt control system of *Drosophila* in Waddington's experiment. (Surely such a restriction to a single property is artificial, since every property is lawfully related to some other property of the same system. However, paying attention to a selected property does not entail denying the existence of other properties.) Make the following assumptions about P:

(i) P has a symmetric (e.g. bell-shaped) distribution in each population of the given lineage;

(ii) the successive generations do not overlap – so that the evolution of the population, as far as P is concerned, can be represented as a denumerable sequence of symmetric distributions;

(iii) there is an optimal value P_f of the given property, i.e. the individuals that come closest to possessing this value of P have the greatest survival chance. For the sake of definiteness assume that P_f lies somewhere to the right of the value P_i of the center of the initial distribution: see Figure. 3.6.

Variation and selection ensure that a gradual shift of the distribution in P to the right will occur as long as the optimal value P_f has not been attained. Indeed only those organisms with a P value close to the optimal P_f will be fit and they will tend to pass that characteristic on to their progeny – not because they want to secure the preservation of their species but because of the blind molecular process at the root of reproduction. As adaptation increases, survivorship increases and spread – i.e. individual variability – decreases. Where the vitalist sees a master plan or "teleonomic project", the evolutionist sees only a random process guided by natural selection. (Cf. Levins, 1968, Ch. 2; Dobzhansky, 1974.)

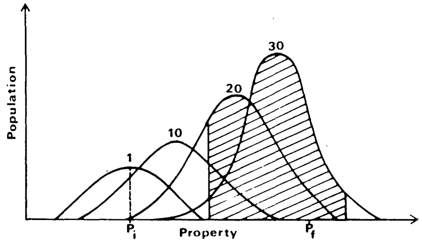

Fig. 3.6. Distribution of P-ness along 30 generations of organisms of a given lineage in a constant environment. The shaded areas represent fractions of survivols. In the beginning a tiny fraction of the total are adapted. At the end survivorship has increased enormously but variability has decreased. Imaginary and exaggerated.

3.3. *Evolution and Coevolution: basic ideas*

We have been referring to evolution without defining the concept. We do not have to look very far: the concept of bioevolution is just a specification of the general concept of history of a system (Ch. 1, Sec. 2.2) to biopopulations (Definition 3.4). That is,

DEFINITION 3.13 The *evolution* of a biopopulation is the history of the latter. I.e. if x is a biopopulation, then

$$\text{The evolution of } x = h(x).$$

What evolve, then, are biopopulations regarded as concrete systems spread out in space and time, rather than either individuals or species. (Individuals develop and species can succeed one another.) If we focus on qualitative changes and disregard intermediate steps, we can construe an evolutionary line as a succession of species or lineage (Definition 1.17).

Before Darwin proposed his theory of evolution by natural selection, bioevolution either was denied or was conjectured to have proceeded in a different way – e.g. by individual adaptation and the inheritance of acquired characters (Lamarck). We adopt of course the core of the Darwinian theory:

POSTULATE 3.4 All populations evolve, and the evolution of each is a process whereby spontaneous (genic) changes ensue in unequally adapted individuals, amongst which the environment selects the best adapted ones.

Selection is called *natural* if it is spontaneous, and *artificial* if controlled by man.

Because biopopulations are not isolated from each other but interact with other biopopulations forming ecosystems, the evolution of each must affect that of others. This process has a name of its own:

DEFINITION 3.14 Two or more populations *coevolve* iff the evolution of each affects that of the other I.e. if x and y are biopopulations, then x and y coevolve iff $h(x \mid y) \neq h(x)$ and $h(y \mid x) \neq h(y)$.

But we just said that every change occurring in any single biopopulation is bound to affect the biopopulations with which it interacts – in particular cooperates or competes. We obtain thus, albeit informally, a result important enough to be dignified with the name

THEOREM 3.1 Every biopopulation coevolves with every other biopopulation in the same ecosystem.

This is why it has been held that the unit of evolution (hence the referent of the theory of evolution) is not so much the monospecific population as the entire ecosystem (Dunbar, 1960). And why not the entire biosphere? These heresies are common sense in our systemic ontology, for any change in one system component is bound to affect every component to which it is coupled. (The only way to escape Theorem 3.1 is to deny that there are ecosystems and so to fly in the face of evidence.) The moral for the building of mathematical models of evolution is clear: Start by modeling the evolution of one biopopulation; proceed to model the coevolution of the (sub)system composed of the given biopopulation and its closest partner(s) or rival(s) – e.g. rock fish and the algae they eat; and aim at modeling the whole ecosystem of interest. Easier said than done!

In view of Definition 3.13, every evolutionary process can be represented as the trajectory of the representative point of the state of a biopopulation (or ecosystem) in its state space. However, it is not at all obvious how to choose the components of the state function spanning that state space. (Cf. Lewontin, 1974.) One possibility is to choose the gene frequencies (actually probabilities) as the coordinates or components of the state function. This is the course adopted by population genetics. It has not been too fruitful because selection operates on phenomes not genomes. (What the environment tolerates or wipes out are whole organisms, not just genomes.) The other extreme is of course to choose only molar or phenotypic variables as components of the state function. But this would leave the primary source of individual variability in the dark. And neither of the above strategies makes room for environmental variables. So we are led to a third approach, namely taking the census counts of the various subpopulations of a given biopopulation in the course of time, and viewing them as the net effects of genic variability and environmental selection. This will be done in the next subsection – with apologies to the biological profession for encroaching on their territory.

3.4. *A Schema of the Evolutionary Process*

We propose to sketch a simple model of evolutionary processes (Bunge 1978a). Consider a biopopulation of organisms such as bacteria of some kind, that reproduce by binary division. Assume that each individual lives one time unit, at the end of which it divides simultaneously with all the other members of the population. Assume also that mutants appear at each generation and that they can be grouped into distinct varieties. Call V_i the ith variety, where $1 \leq i \leq n$, and count the population of each variety at each generation. Further, call N_t^i the population of variety V_i at time (generation) t. If the fraction of each generation that dies without leaving offspring is $d_i < 1$, then the population of variety V_i at time $t + 1$ is

$$N_{t+1}^i = 2(1 - d_i)\, m_{ii}\, N_t^i, \tag{3.1}$$

where m_{ii} is the probability that division be not accompanied by mutation, and the factor 2 accounts for the division of each organism into two new individuals.

The previous formula assumes that all of the offspring of generation t belong to the same variety. In point of fact the number of individuals of variety V_i at time $t + 1$ will differ from the above by two terms: the fraction leaving the given variety and the fraction entering it, in both cases by mutation. Call m_{ij} the probability per unit time of a mutation from variety V_i to variety V_j. These probabilities are subject to the normalization condition

$$\sum_j m_{ij} = 1 \quad \text{for every } 1 \leq i \leq n. \tag{3.2}$$

The average number of defectors from variety V_i between times t and $t + 1$ will be

$$D^i = 2 \sum_{j \neq i} m_{ij}(1 - d_i)N_t^i. \tag{3.3}$$

And the converts to variety V_i in the same time interval number

$$C^i = 2 \sum_{j \neq i} m_{ji}(1 - d_j)N_t^j, \tag{3.4}$$

for they will be drawn from all varieties but V_i. The factor 2 in D^i and C^i shows that we are making the additional hypothesis that mutants come in pairs – i.e. that if an organism is mutant so is its sister.

Collecting (3.1), (3.3) and (3.4) we obtain the net average population of variety V_i at time $t - 1$:

$$\begin{aligned} N_{t+1}^i &= 2m_{ii}(1 - d_i)N_t^i - D^i + C^i \\ &= 2\left[m_{ii}(1 - d_i) - \sum_{j \neq i} m_{ij}(1 - d_i)\right]N_t^i \\ &\quad + 2 \sum_{j \neq i} m_{ji}(1 - d_j)N_t^j. \end{aligned} \tag{3.5}$$

Because of the normalization condition (3.2) of the mutation probabilities, the total probability of mutation from V_i is

$$\sum_{j\neq i} m_{ij} = \sum_{j} m_{ij} - m_{ii} = 1 - m_{ii}. \tag{3.6}$$

Introducing this value into (3.5) we are finally left with

$$N^i_{t+1} = 2(2m_{ii} - 1)(1 - d_i)N^i_t + 2\sum_{j\neq 1} m_{ji}(1 - d_j)N^j_t. \tag{3.7}$$

This system of n linear difference equations summarizes our model of evolution. The solution to these equations can be obtained as follows. Set

$$\begin{aligned} a &= \|a_{ij}\| = \|2(2m_{ii} - 1)(1 - d_i)\delta_{ij}\| \\ b &= \|b_{ij}\| = \|2m_{ij}(1 - d_i)(1 - \delta_{ij})\|, \end{aligned} \qquad N_t = \begin{Vmatrix} N^1_t \\ N^2_t \\ \vdots \\ N^n_t \end{Vmatrix}, \tag{3.8}$$

where $\delta_{ij} = 1$ iff $i = j$ and 0 otherwise. (The transpose of N_t is the value of the state function of the system at t.) The system (3.8) can be condensed into the matrix difference equation

$$N_{t+1} = (a + b^T)N_t, \quad \text{where} \quad \|b_{ij}\|^T = \|b_{ji}\|. \tag{3.9}$$

Iterating (3.9) we find the general equation of evolution

$$N_{t+k} = (a + b^T)^k N_t, \quad \text{where} \quad k \in \mathbb{N}. \tag{3.10}$$

The solution to this equation is

$$N_t = (a + b^T)^t N_0, \tag{3.11}$$

where N_0 is the column matrix of the initial populations of the n varieties being considered.

Suppose that all of the entries of the evolution matrix $a + b^T$ are positive, and that initially a single variety is present. Then all the other varieties can emerge simultaneously at the next generation, and the mutation-and-selection process proceeds relentlessly. Every one of the n varieties prospers once emerged, and the prosperity of each is conducive to that of all. (The only qualitative change in this process can be induced by a sudden environmental change causing some death rates to jump to unity.) But in general the process will not be explosive: while some entries of the evolution matrix may be positive, others may be zero or negative. An overall negative matrix corresponds of course to extinction.

As long as the death rates d_i and the mutation probabilities m_{ij} are not specified, the model is a phenomenological skeleton. Let us proceed to flesh it out.

3.5. *The Underlying Mechanism*

Let us now specify the architecture of our evolving organisms as well as their mutability (the m_{ij}) and viability (the d_i). We assume that the n varieties of our biopopulation differ by the composition or arrangement of a fixed number of modules or basic units that can be repeated. For the sake of simplicity we suppose that there are just two kinds of module, which we call 0 and 1. Thus if each entity is composed of four such modules arranged differently, we obtain a total of $n = 2^4 = 16$ varieties, namely 0000, 1000, 0100, 0010, 0001, 1100, 0110, 0011, 1010, 0101, 1001, 1110, 0111, 1011, 1101, and 1111. The general formula for a variety whose members are composed of m modules is $abc\ldots m$, where each letter is a binary digit. So much for architecture.

Every change in at least one of the m binary digits occurring in the formula for a variety is a mutation. Thus a mutant will differ from its parent organism either by the total number of 0's (or 1's) or by the order of 0's or 1's. Thus in the above example the transitions 0000 → 1000, 0100 → 0110, and 0111 → 1111 are mutations and, at the same time, changes in variety. Of course not all mutations are equally probable. We shall determine certain relations among mutation probabilities with the following considerations on viability.

Enter the environment. We lump all of the environmental factors into a single real valued function e with values in the $[-1, 1]$ real interval. And we assume that the probability that an organism belonging to variety V_i survives up to and including division is symmetrical about the origin. More precisely, we assume that the death rates d_i in (3.1), far from being constant, depend upon the environmental variable e in the following way:

$$1 - d_i = \begin{cases} v_i(1 - e^2) & \text{for } -1 \leq e \leq 1 \\ 1 \text{ otherwise}, \end{cases} \tag{3.12}$$

where $0 \leq v_i \leq 1$ for each variety V_i.

Since v_i is characteristic of each variety and is environment-independent, we call it the *adaptedness* of organisms of the variety V_i. The factor $(1 - e^2)$ represents the selection pressure effected by the environment. A substantial increase or decrease in e will have a considerable impact on the fraction $1 - d_i$ of a given population surviving until the next division. In particular, if a catastrophe occurs ($e = \pm 1$), no survivors are left, i.e. $d_i = 1$ for all i. On the other hand if the environmental conditions are optimal ($e = 0$), then the fraction v_i of individuals of variety V_i survive long enough to divide. The variable e is, in sum, the causal or nonstochastic component of evolution.

We introduce now an assumption that will allow us at least to rank the viability values. Our hypothesis is that the more varied the composition of an organism the better its chances of survival. Thus in the case $m = 2$, where we have only the varieties 00, 01, 10, and 11, we set

$$\begin{aligned} v_1 &= v_4 \equiv v && \text{for 00 and 11} \\ v_2 &= v_3 = \alpha v && \text{with } \alpha > 1 \text{ for 01 and 10.} \end{aligned} \tag{3.13}$$

Finally we relate viability to mutability, namely thus: we postulate that a mutation is the more probable the less viable its product is. (This assumption is in keeping with the well known generalization that most mutants are lethal.) More precisely, we assume

$$m_{ij} \geq m_{ik} \quad \text{if and only if } v_j \leq v_k. \tag{3.14}$$

We can now build the matrix of the mutation probabilities in the simple case where $m = 2$, whence $n = 4$. In this case the viabilities are those indicated in (3.14). Hence the reproduction chances are

$$\begin{aligned} 1 - d_1 &= 1 - d_4 = v(1 - e^2) \\ 1 - d_2 &= 1 - d_3 = \alpha v(1 - e^2). \end{aligned} \tag{3.15}$$

The hypothesis (3.14), that most mutations are deleterious, together with the assumption (3.13) on the adaptedness values, entails

$$m_{41} = m_{14}, \qquad m_{32} = m_{23} = m \tag{3.16}$$

(where this m is not to be confused with the number of kinds of modules per organism, which we have taken to be 2), and

$$\begin{aligned} m_{21} &= \beta_1 m_{12}, & m_{31} &= \beta_1 m_{13} \\ m_{24} &= \beta_2 m_{42}, & m_{34} &= \beta_2 m_{43}, \end{aligned} \tag{3.17}$$

with $\beta_1, \beta_2 > 1$. We simplify by setting $\beta_1 = \beta_2 = \beta$, and so are left with

$$\begin{aligned} m_{21} &= \beta m_{12}, & m_{31} &= \beta m_{13} \\ m_{24} &= \beta m_{42}, & m_{34} &= \beta m_{43}. \end{aligned} \tag{3.18}$$

Since module permutations are far less radical than changes in composition, we make the further simplifying assumptions that

$$m_{12} = m_{13}, \qquad m_{24} = m_{34}. \tag{3.19}$$

Similary, we posit that the variety 01 is just as stable as 10, and that 00 and 11 are equally stable:

$$m_{22} = m_{33}, \qquad m_{11} = m_{44}. \tag{3.20}$$

Our final assumption is that the mutations between the extreme varieties 00 and 11 proceed via the intermediate species 01 and 10, i.e.

$$\begin{aligned} m_{14} &= m_{12}\cdot m_{24} + m_{13}\cdot m_{34} \\ m_{41} &= m_{42}\cdot m_{21} + m_{43}\cdot m_{31}. \end{aligned} \tag{3.21}$$

A first consequence of the above assumptions is

$$\begin{aligned} m_{21} &= m_{31}, \qquad m_{42} = m_{43} \\ m_{14} &= 2m_{12}\cdot m_{24} = m_{41} = 2m_{21}\cdot m_{42}. \end{aligned} \tag{3.22}$$

Finally we use the normalization condition (3.6) which, together with the previous equalities, yields the mutability matrix in terms of m_{11}, m_{22} and m:

$$\|m_{ij}\| = \left\| \begin{matrix} m_{11} & \dfrac{(1-m_{11})}{(3-m_{22}-m)} & \dfrac{(1-m_{11})}{(3-m_{22}-m)} & (1-m_{11})\cdot\dfrac{(1-m_{22}-m)}{3-m_{22}-m} \\ \frac{1}{2}(1-m_{22}-m) & m_{22} & m & \frac{1}{2}(1-m_{22}-m) \\ \frac{1}{2}(1-m_{22}-m) & m & m_{22} & \frac{1}{2}(1-m_{22}-m) \\ (1-m_{11})\cdot\dfrac{(1-m_{22}-m)}{3-m_{22}-m} & \dfrac{(1-m_{11})}{(3-m_{22}-m)} & \dfrac{1-m_{11}}{3-m_{22}-m} & m_{11} \end{matrix} \right\| \tag{3.23}$$

We proceed now to trace the evolution of our four-variety biopopulation. To compute their respective numbers at successive generations we must know what their initial numbers were. Suppose a single variety is initially present, say V_1 or 00. Call $N_0^1 = N$ its initial population. Then by (3.7) one generation later the average numbers are

$$\begin{aligned} N_1^1 &= 2(2m_{11} - 1)(1 - d_1)N \\ N_1^2 &= \frac{2(1 - m_{11})}{3 - m_{22} - m}(1 - d_1)N \\ N_1^3 &= N_1^2 \\ N_1^4 &= (1 - m_{22} - m)N_1^2. \end{aligned} \tag{3.24}$$

If $m_{11} \leq \frac{1}{2}$ or $d_1 = 1$, the first variety becomes extinct forthwith. And if $m_{11} = 1$ while $d < 1$, V_1 prospers without change. The *necessary and sufficient condition* for the evolutionary process to occur is then

$$\tfrac{1}{2} < m_{11} < 1 \quad \text{and} \quad 0 \leq d_1 < 1. \tag{3.25}$$

If this condition obtains then the lower bound of the population of varieties V_2 and V_3 at first generation is

$$\tfrac{2}{3}(1 - m_{11}) \cdot (1 - d_1)N.$$

Since this number equals at least 2, we infer that the lower bound of the stability of the parent variety is given by

$$m_{11} \geq 3/(1 - d_1)N. \tag{3.26}$$

Because the upper bound of m_{11} is 1, we infer that for a change of variety to occur it is necessary that

$$N > 3/1 - d_1. \tag{3.27}$$

For a low death rate of the parent variety, as few as four members of it could give rise to the differentiation process.

The above conditions concern only varieties V_2 and V_3. For variety V_4 to emerge a more severe condition must be met, as we gather from the last of equations (3.24), namely

$$(3.25) \ \& \ (m_{22} + m < 1) \quad \text{or, equivalently,} \quad (3.25) \ \& \ (m_{21} + m_{24} > 0).$$

Finally we write the general evolutionary equations (3.7) for an arbitrary generation (t value). Using the mutation matrix (3.23), we obtain the following system of first order linear difference equations:

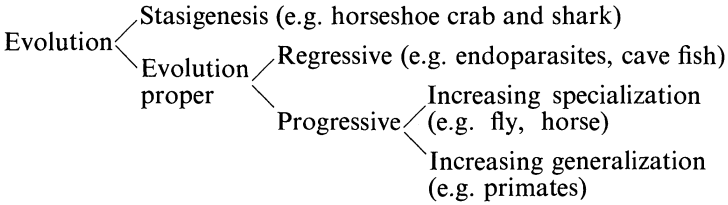
$$\begin{aligned} N_{t+1}^1 = {} & 2(2m_{11} - 1)(1 - d_1)N_t^1 + (1 - m_{22} - m)(1 - d_2)N_t^2 \\ & + (1 - m_{22} - m)(1 - d_3)N_t^3 \\ & + \frac{2(1 - m_{11})(1 - m_{22} - m)}{3 - m_{22} - m}(1 - d_4)N_t^4 \end{aligned}$$

$$\begin{aligned} N^2_{t+1} &= 2(2m_{22} - 1)(1 - d_2)\, N^2_t \\ &\quad + \frac{2(1 - m_{11})}{3 - m_{22} - m}(1 - d_1)N^1_t + 2m(1 - d_3)N^3_t \\ &\quad + \frac{2(1 - m_{11})}{3 - m_{22} - m}(1 - d_4)N^4_t \\ N^3_{t+1} &= 2(2m_{33} - 1)(1 - d_3)N^3_t + \frac{2(1 - m_{11})}{3 - m_{22} - m}(1 - d_1)N^1_t \\ &\quad + 2m(1 - d_2)N^2_t + \frac{2(1 - m_{11})}{3 - m_{22} - m}(1 - d_4)N^4_t \\ N^4_{t+1} &= 2(2m_{44} - 1)(1 - d_4)N^4_t \\ &\quad + \frac{2(1 - m_{11})(1 - m_{22} - m)}{3 - m_{22} - m}(1 - d_1)N^1_t \\ &\quad + (1 - m_{22} - m)(1 - d_2)N^2_t + (1 - m_{22} - m)(1 - d_3)N^3_t. \end{aligned}$$

This is the kind of linear algebra problem that computers love. But its solution is of no philosophical interest. What are of philosophical interest are the following points. First, the general evolution equations (3.7) can be turned, from a mere descriptive black box, into a mechanismic model representing the mutation-selection process – a model capable of making precise predictions about a certain evolutionary line. Second, this is a peculiarity not of our problem but of the synthetic theory of evolution, which is not a predictive theory unless it is adjoined precise data and hypotheses concerning the genetic makeup and the environment of the organisms concerned. (We shall come back to this problem in Vol. 6.)

3.6. *Bioprogress*

Evolutionary biologists agree that all modern complex organisms descend from primitive organisms: recall Figure 3.2. So, there would seem to be no doubt that evolution has been progressive. Not so fast. First of all, the following kinds of evolutionary process are usually distinguished:



Evolution
Stasigenesis (e.g. horseshoe crab and shark)
Evolution proper
Regressive (e.g. endoparasites, cave fish)
Progressive
Increasing specialization (e.g. fly, horse)
Increasing generalization (e.g. primates)

Some lineages, then, have advanced over certain periods while others have not. The second problem is that there is no agreement on the very notion of bioprogress – the more so since progress through increasing specialization is sure to lead to stagnation or extinction.

A number of alternative definitions of bioprogress have been proposed (cf. Williams, 1966, Bowler, 1976). Here are some: bioprogress is increasing histological differentiation, morphological complication, survivorship, adaptability, freedom from the environment, or amount of genetic information. All of these proposals presuppose that progress is global rather than partial (in particular respects), and none of them lends itself easily to quantitation. In particular, the information-theoretic definition is pseudoquantitative, as there is no unambiguous and objective way of measuring or computing the "quantity of information stored in an organism" (Lwoff, 1962; Apter and Wolpert, 1965). After all, biosystems are not identical with their genomes, and the latter are more than just information processing devices.

We shall take it that bioprogress consists in increasing biovalue, and shall proceed to refine the distinction (Ayala, 1974) between uniform (relentless) progress, on the one hand, and overall (net, average) progress on the other. Our elucidation will make use of the concept of system progeny (Definition 1. 15(v)) and Definition 3.9 of biovalue. Since the former was framed for systems in general, we shall first adapt it to biopopulations; and this adaptation will involve the notion of a variable collection, i.e. one with changing membership (Vol. 3, Definition 5.13). Let us then start with

DEFINITION 3.15 Let $\mathscr{P} = \{p_t \mid t \in T\}$ be a family of biopopulations of a certain kind, indexed by time (T). For any $p_0, p_t \in \mathscr{P}$, where $t > 0$,

(i) p_t *descends* from p_0, or $p_0 \prec p_t$, iff every member of p_0 descends from some member(s) of p_0;

(ii) the *progeny* of p_0 is the family of biopopulations that descend from p_0:

$$P(p_0) = \{p_t \in \mathscr{P} \mid p_0 \prec p_t\}.$$

We now add the idea that, if x and y are successive populations, x constitutes an improvement over y in a certain respect z if x performs better than y in doing z. More precisely, we propose

DEFINITION 3.16. Let p_0 be a biopopulation of organisms of a certain kind K, and call $P(p_0)$ the progeny of p_0. Further, call Σ a certain kind of subsystem (e.g. organ) of every member of p_t in $P(p_0)$, and assume that all the subsystems of that kind perform (roughly) the same function(s). Then

(i) the K's have *advanced on the whole* with regard to Σ between p_0 and p_t, for $t \gg 0$, iff the value of subsystem of kind Σ for the members of p_t is significantly greater than its value for the members of p_0;

(ii) the K's have *advanced uniformly* along $P(p_0)$ with regard to Σ between p_0 and p_t, for $t \gg 0$, iff the value of subsystem of kind Σ for the members of every population p_u in $P(p_0)$, between p_0 and p_t, is greater than its value for the immediate ancestors of the p_u's.

Whereas the first clause elucidates the notion of net or average progress, the second clarifies that of uniform progress. Uniform progress implies net progress but not conversely: i.e. there may be temporary setbacks in a progressive lineage,

Finally we make

DEFINITION 3.17 Under the nomenclature and assumptions of Definition 3.16, the K's have *progressed globally* between p_0 and p_t iff the value of every function of the members of p_t is greater than the value of the corresponding function for the members of p_0.

Remark 1 The above definitions do not discriminate between progress in a roughly constant environment, therefore at the cost of severe selection, and the accidental improvement of environmental conditions (or preadaptation). *Remark 2* Our definitions involve the concept of biovalue, hence that of goodness. Indeed, x is *good* for $y =_{df}$ the value of x for y is positive. However, these concepts are biological in our system, because biovalue was defined in strictly biological terms (Definition 3.9). Instead of injecting an anthropomorphic concept of value into biology, we have tried to derive an objective concept of value from the biological concept of health of a biosystem,

So much for definitions. Now is the time for commitment. Is there progress in evolution and, if so, is it universal and global or local and partial? According to some philosophers and biologists, from Aristotle to Lamarck, bioevolution is gradual and slow progress toward perfection. This hypothesis presupposes that the environment has remained constant for over 4 billion years, or that it has changed for the better of every species. This presupposition has been refuted by the evidence for continental drifts, glaciations, desertifications, earthquakes, and the depletion of a number of resources. While some such changes have been favorable to some species (those preadapted to the new environments), and even to the emergence of new species, they have been fatal to others. In any case most species have become extinct instead of persisting on the road of improvement.

Another presupposition of the hypothesis of universal and global progress is that there exists a fixed goal – an ideal or paradigm – towards which successive generations move. This hypothesis would make sense in a Platonic biology, where the archetype is perfect, every real organism being a sort of blurred carbon copy of the former. But of course there is no such thing as Platonic biology, although there are vestiges of Platonism in biotaxonomy. The very notion of an immaterial object – such as the Idea of the Perfect Mosquito – guiding the evolution of concrete things is inconsistent with the ontology of modern science. (Cf. Vol. 3, Introduction and Ch. 2.) Besides, since the environment changes rather erratically and sometimes dramatically, if there were a target then it should be moving rather than fixed, and so evolutionary processes zig-zag rather than go in a definite direction.

In sum, the biosphere does not obey the so-called "law of progress". Progress, when it *does* occur, is a trend not a law, and one occurring in *some* lineages, in *some* respects, and for *some* time. In the biosphere, just as in the sociosphere, there are not only progressives (e.g. mammals) but also conservatives (e.g. ants) and reactionaries (e.g. lice). Besides, whereas many progressives have become extinct, some conservatives are still around: drastic environmental changes and fierce competition can wreck the most brilliant careers.

For all the above reasons, the most we can assert is

POSTULATE 3.5 Every biospecies advances in some respects during some periods and in certain environments.

That is, bioprogress is often real but always partial, relative, and temporary. It is *partial* because an improvement in some respect(s) may constitute a drawback in other(s); e.g. an increase in size may confer greater strength but it also calls for greater energy consumption and less mobility. Progress is *relative* to the environment – moreover it can be active or passive: earned by mutation and selection, or won in the lottery of environmental cataclysms. And progress is *temporary* or limited to definite periods rather than eternal.

4. CONCLUDING REMARKS

The traditional biometaphysics are vitalism and mechanism. The strength of the former lies in its ability to ask questions, some of them pertinent, that the latter fails to answer. Whereas classical vitalism has hardly evolved, mechanism has. Two kinds of mechanism are popular today: (a) *physicochemicalism*, or the thesis that organisms are just physicochemical systems, and (b) *machinism*, or the thesis that organisms are machine-like systems, hence fashioned after a design or plan, and acting in a goal-seeking manner.

Physicochemicalism is the heir to traditional mechanism, and machinism a hybrid of mechanism and vitalism. Whereas the model of the first is the chemical reactor, that of the second is the computer. Neither of these biometaphysics is consistent with the whole of biology, although physicochemicalism has been fruitful where machinism has been sterile. Physicochemicalism is incompatible with biology because it denies emergence and levels, and machinism because it takes for granted and posits plans and goals where there are none.

The alternative we propose is *biosystemism*, or the application of systemism (Ch. 1, Sec. 4.2) to the study of life. Biosystemism recognizes the *bios* as an emergent level rooted to the chemical one. Therefore it accepts the lay difference between living and nonliving – denied, e.g. by Pirie (1960), Kendrew (1966) and Keosian (1968) – as well as the molecular-biological account of the self-assembly of biosystems from biochemical precursors, and the theory of evolution by genic changes and natural selection.

We are faced then with four different biometaphysics, each with its accompanying problem circle, method, and goal: see Table 3.1. The oldest and most persistent of them is vitalism, which is also the most popular biophilosophy. Actually there are two kinds of vitalism: ontological and methodological. The former states that organisms are distinguished by some immaterial principle, the latter that they are so complex and variable, that they cannot be tackled with the ordinary methods of science. Ontological vitalism has been pronounced dead long ago, even by biologists who continually lapse into it – such as Monod (1970) and Jacob (1970) when fantasizing about the *project téléonomique* of every organism. On the other hand the claim that organisms cannot be studied by the ordinary scientific method but call for a special method (i.e. methodological vitalism) is still very much alive except among molecular biologists (Bunge, 1973a, Ch.3).

As for machinism, its distinctive thesis is that organisms are like machines in their having a design or plan and a purpose. However, two kinds of machinism must be distinguished: verbal and serious. Verbal machinism restricts itself to repeating uncritically the organism-machine

TABLE 3.1

Four approaches to the study of life

		Mechanism		
	Vitalism	Machinism	Physico-chemicalism	Biosystemism
Ontological Framework	Life transcends matter and is guided by an immaterial principle	Organisms are machine-like: they have plans and goals.	Organisms are physicochemical systems.	Organisms are *sui generis* systems composed of biochemical systems and possessing emergent properties and laws.
Problem Circle	'What is it for?' questions.	'What is it for?' and 'How does it work?' questions.	'How is it composed?' and 'What are its properties?'	All biological problems, in particular regarding subsystems, their self-assembly, and evolution.
Method	Description of organism as a whole.	Physico-chemical methods plus building of analogs.		The whole array of particular methods of the various chapters of natural science.
Goals	Intuitive understanding of the whole	Technology-wise explanation and forecast.	Physicochemical explanation and prediction.	Biological explanation and prediction.

analogy and to warning that biology may learn more from engineering that from physics and chemistry (Polanyi, 1968). This kind of machinism can be discarded by noting that biology does not have a single law statement, let alone theory, containing the concepts of plan (or design) and purpose. (Even the most serious attempt to incorporate the concept of goal-directedness into biology, namely that of Sommerhoff (1974), fails to mathematize correctly that concept as well as to exhibit examples of laws and theories where the concept occurs.)

Serious contemporary machinism is the heir to Descartes and La Mettrie and culminated with the theory of self-reproducing automata (von Neumann, 1966). It is rather popular with the computer science crowd, as can be seen by scanning the *J. Computer and System Sciences.* This approach has stimulated, in particular, biological applications of the theories of automata and information. However, three decades of work along this line have yielded precious little; in particular, it has not contributed to the molecular biology revolution or to evolutionary biology. No wonder, for machinism skips the chemical level and ignores history: it thinks in terms of ready made systems rather than of enzymatic reactions or natural selection.

Machinism combines the negative aspect of mechanism (downward reductionism) whith the negative aspect of vitalism (upward reductionism). Its sole virtue is its clarity. Surely, machinism has stimulated the design and construction of ingenious mock organisms, such as Grey Walter's mechanical tortoise. However, since such artifacts are avowedly very different from the real thing they simulate, they do not teach us much about the latter. The only use of biosimulates is as toys or as slaves. In short, machinism is mistaken because it ignores that organisms are composed of chemical systems, rather than electromagnetic ones, and assigns them a property very few animals exhibit, namely that of seeking goals, and another that none have, namely optimal design or perfection.

As for physicochemicalism, it has undoubtedly been a fertile biophilosophy. In fact it has stimulated the birth of entire branches of science, such as biophysics, biochemistry, molecular biology, and bioengineering. In particular molecular biology might not have been born but for the hypothesis that chemical (in particular enzymatic) reactions constitute the root if not the marrow of life. In any case this conjecture sparked off, among other things, the chemical theory of heredity, which was the initial phase of molecular biology. (On the other hand physicalism, which tried to skip the chemical level, failed to contribute anything to the developments that culminated in the discovery of the double helix and the genetic "code": see Olby (1974). This is not to deny that physics, in particular X-ray crystallography, was indispensable. But it is one thing to use physical techniques and another to conceive of the organism as a physical system.)

Molecular biology, largely an offspring of the physicochemicalist branch of biometaphysics, has gone beyond digging up the chemical roots of life: it has shown that a number of properties that used to be regarded as typically biological – such as metabolism and self-reproduction – are actually biochemical. However, in their eagerness to rid biology of myth and explain it in terms of chemistry, molecular biologists have often stressed composition at the expense of organization or structure, as well as heredity to the detriment of environment. Consequently they have often overlooked the multi-level structure of the organism – organelle, cell, organ, multicellular organism. For this reason, although molecular biology is indispensable for explaining evolution, it is not sufficient: phenotypes and environments are just as important as genotypes. After

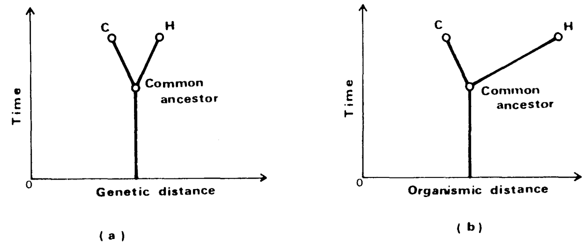


Fig. 3.7. Humans (H) and chimpanzees (C) are genetically about as different as two subspecies of mice (*a*). They differ mainly at the organ level (*b*), particularly in respect of the nervous system, hence of behavior. See King and Wilson (1975).

all, man and chimpanzee are hardly distinguishable at the biochemical level: see Figure 3.7.

To conclude. Vitalism is untenable but it has bequeathed us two important true principles:

V1 Life is emergent: it transcends the physico-chemical level.

V2 The biosphere has a level ("hierarchical") structure going from cell to organ to organism to population to ecosystem.

Physicochemicalism denies these principles but contributes another two important true hypotheses:

M1 Life emerged by the self-assembly of macromolecules.

M2 Some physical and chemical laws continue to operate in organisms.

Biosystemism adopts all four principles and adds its own:

S1 Organisms are systems composed of biochemical systems and possessing emergent properties.

S2 Every level in the biosphere has its own laws: laws of cells, of organisms, of populations, and of ecosystems.

S3 The units of biological study are the organism-in-its environment and its various subsystems (molecules, cells, organs) and supersystems (population, ecosystem, biosphere).

So much for the ontology of biosystemism. As for its methodology, it is epistemic reductionism, which is perfectly compatible with ontological pluralism (Bunge, 1977f), and boils down to

RULE 3.1. Each bioentity must be studied on its own level and should be explained with the help of its adjoining levels.

Thus an organ should not only be studied on its own level but should also be analyzed both downward (in terms of its subsystems) and upward (in terms of the entire organism in its environment). This holds particularly for the human brain, which is not only a neural system but also a subsystem of a component of social systems. But this is the story to be told next.

CHAPTER 4

MIND

The present chapter deals with one of the oldest, most intriguing, and most perverse of all the problems lying in the intersection of philosophy and science, namely the so-called mind-body problem. This is the system of questions about the nature of mind and its relations to matter.

Some eminent thinkers – notably Spencer (1862), E. du Bois-Reymond (1872), and Popper and Eccles (1977) – have pronounced the problem to be insoluble. I submit that part of the problem is that it is usually formulated in inadequate terms – namely those of ordinary language. These are inadequate not only because ordinary language is notoriously poor and inexact, to the point of being of little use in investigating the problem of matter, but also because it begs the question. Indeed European languages are loaded with a preconceived solution to the problem of mind, namely psychophysical dualism, or the doctrine that mind is something apart from matter. The very expression 'mind-body problem' suggests that mind and body are distinct entities on the same footing – i.e. things. We must then look to science for inspiration.

In science we do not speak of the motion-body problem, or of the reaction-substance problem, or of the digestion-digestive tract problem, or of the mobility-society problem. We speak instead of the motion *of* bodies, the reaction *of* chemicals, the digestive functions *of* the digestive tract, and the mobility *of* a society. We do not reify properties, states, or events – except when it comes to the properties, states, and events of the nervous system. We shall close this gap, that keeps the study of mind a scientific anomaly in the grip of myth, by replacing ordinary language by state space language, which is mathematically precise and is shared by science and scientific ontology.

Another difficulty besetting the so-called mind-body problem is the extreme youth of neuroscience: recall that Ramón y Cajal's neuronal hypothesis is less than one century old. Surely there were important sporadic discoveries in earlier times, starting with Hippocrates' hypothesis that the brain – rather than the heart or the liver – is the organ of emotion and thought. However, it is only in recent years that a concerted attack at all levels has been launched (Worden *et al.* (Eds.), 1975).

A third difficulty is that, far from being a strictly scientific problem, ours is also a philosophical one. In fact it is a traditional metaphysical problem and the one that has aroused the greatest passion – hence also the greatest caution. Moreover its very formulation presupposes a number of notions that are far from clear in traditional metaphysics, in particular those of substance, property, state, event, emergence, and level of organization. Thus any argument as to whether or not there is a mental substance, or whether there are mental states that fail to be brain states, calls for a prior elucidation of the general concepts of substance and state – an elucidation that most philosophers do not care to perform.

Fourth and last, another reason for the backward state of research into the so-called mind-body problem is that it belongs not only to science and to philosophy but also to ideology. Indeed all religions and some political ideologies have a vested interest in it and some even claim exclusive ownership. So, far from being interested in the investigation of the problem, they are anxious to have us accept their own ready-made solution.

In short, there have been many obstacles in the way of a scientific study of the problem. Fortunately some of these obstacles are disappearing rather quickly, and the science of mind – i.e. psychology – is making great strides. Three formerly separate currents are converging on it: neuroscience, psychology, and philosophy. Indeed, over the past few decades neurophysiologists and neurologists have begun to study the mental functions of neural systems, physiological psychologists have started to disclose the neural mechanisms "mediating" behavior, and philosophers have begun to analyze some of the key concepts involved in the question, and to overhaul the ancient doctrine that mental functions are a kind of bodily functions. There is still a long way to go before maturity is attained, but the science of mind has finally made a start.

This chapter, like the others in this book, will offer only a general framework – but, of course, one consistent with the basic ideas of system, property, law, and change prevailing in science and expounded earlier in the work.

1. CENTRAL NERVOUS SYSTEM

1.1. *Philosophical Background*

Perceiving, feeling, remembering, imagining, willing, and thinking are usually said to be mental states or processes. Since in science and in our ontology there are no states or processes in themselves, but only states *of* some entity and processes *in* some thing, we must ask *what* minds – i.e. what is the thing that perceives, feels, remembers, imagines, wills, and thinks. This is the very core of the so-called mind-body problem, i.e. the identification of the subject or referent of the mentalist predicates.

Those who hope the mind-body problem to be soluble have proposed two solutions to it: that what does the minding (perceiving, feeling, thinking, etc.) is the mind (or soul or spirit), and that it is the brain. According to the former the mind is an immaterial entity wherein all mental states and processes occur: feelings, memories, ideas, and the like would be in or of the mind, which would in turn be an entity separate from the body. According to the second answer the mind is not a separate entity but a set of brain functions: perceiving, imagining, thinking, and the like would be brain processes. The former thesis is called *psychophysical dualism*, the latter *materialism* or *naturalism*.

However, there are a number of varieties of dualism and of materialism. (Cf. Vesey, 1964; Smythies, 1965; Armstrong, 1968; O'Connor, 1969; Borst, 1970; Popper and Eccles, 1977; Margolis, 1978.). Our main task in this chapter is not to discuss them but to formulate a version of materialism consistent with the principles laid down in the previous chapters and in Vol. 3 of this work. This is *emergentist materialism*, or the doctrine according to which (*a*) all mental states, events and processes are states of, or events and processes in, the brains of vertebrates; (*b*) these states, events and processes are emergent relative to those of the cellular components of the brain, and (*c*) the so-called psychophysical (or psychosomatic) relations are interactions between different subsystems of the brain, or among them and other components of the organism (Bunge, 1977e). This kind of materialism is monistic with respect to substance and pluralistic with respect to properties.

Here are some reasons for favoring emergentist materialism:

(i) because it eschews the ghostly mental substance without thereby denying mental facts, emergentist materialism is *compatible with the scientific approach*;

(ii) emergentist materialism – as we hope to show – is *free from the fuzziness that characterizes dualism* with its talk of an immaterial mind and of "correlations" between it and the body;

(iii) unlike dualism, emergentist materialism is *consistent with the general concepts of state and event that can be gleaned from all the sciences*. (On the other hand according to dualism mental states would be the *only* states that fail to be states of some thing, and mental events the *only* events that fail to be changes of state of some thing – this being why dualism agrees more with theology than with science.)

(iv) Unlike dualism, emergentist materialism *fosters interaction between psychology and the other sciences*, in particular neuroscience, and this precisely because it regards mental events as special biological events;

(v) unlike dualism, which digs an unbridgeable chasm between man and beast, emergentist materialism *accords with evolutionary biology*, which – by uncovering the gradual development of mental faculties along certain lineages – refutes the complacent superstition that only Man is endowed with Mind;

(vi) unlike dualism, which postulates an unchanging mind, emergentist materialism *agrees with developmental psychology* and neurophysiology, which exhibit the gradual maturation of the brain and behavior.

The only drawback to emergentist materialism is its so far not having been formulated in a precise and detailed way. Indeed, emergentist materialism is little more than a programmatic hypothesis with enormous heuristic power. We shall try and remedy this shortcoming in the course of this chapter, by building a general theory of the mind consistent not only with our ontological principles but also with current neuroscience and psychology.

1.2. *Neural Units*

We shall deal throughout this chapter with systems of a special kind, namely organisms endowed with nervous systems. And we shall pay special attention to animals endowed with a central nervous system, or CNS for short. Nervous systems come in a number of degrees of complexity, from primitive worms with half a dozen neurons, to insects with about 100,000, to human with nearly a hundred billion (i.e. 10^{11}). The corresponding behavior levels range from automatic to highly creative. And the varieties of inner life from nil to extremely rich. Since the lower forms of nervous system functioning and animal behavior are generally recognized to be explainable along strictly biological lines, we shall concentrate on the higher functions – i.e. on those which, according to popular belief, require the presence of a soul, spirit, or mind inaccessible to science.

The following levels may be distinguished in a CNS:

Subcellular: neuron's membranes, synaptic boutons, dendrites.

Cellular: neurons and glial cells.

Neural microsystems: multineuronal systems (fixed or itinerant assemblies of thousands or millions of neurons in primates).

Neural macrosystems: systems of thousands of neural microsystems. In primates the following sublevels are distinguished:

> Uncommitted cortex, somethetic system, visual and hearing systems, temperature regulating system, etc.;
> cerebral hemispheres;
> brain;
> central nervous system (CNS), or brain *cum* spinal cord;
> neuroendocrine system (NES), or nervous system *cum* endocrine glands (e.g. pituitary and adrenals).

Every mental process presumably engages millions of neurons and occurs not only at the neural system level but also at the cellular and subcellular levels. Moreover, given the strong coupling between the CNS and the rest of the body, every mental act is bound to engage also some non-nervous tissue. E.g., voluntary movement is an activity not only of certain neural systems but also of certain muscles and endocrine glands. Thus the various neural systems (micro and macro) can be distinguished from one another but they cannot be detached from each other or from the rest of the body, They do the minding but not in isolation from other subsystems of the body.

While some neural systems have permanent components others don't. Thus the visual system has a constant composition, i.e. is composed of anatomically identifiable subsystems – the eyes, the optic nerves, the optic tracts, the lateral geniculate nuclei, and the visual cortex. Other neural systems may not have constant components and so may not be carved out by the surgeon: far from having a constant location, they may be itinerant neuron assemblies formed just for the occasion (Craik, 1966; Bindra, 1976). See Figure 4.1.

We shall call a *psychon* any neural unit capable of discharging mental functions of some kind. There are three main views concerning the nature and size of psychons: neuronism, holism, and systemism. According to neuronism single neurons may possess certain mental abilities – e.g. that of issuing commands. There is no evidence for this view. Holists, on the other hand, assume that nothing short of the whole brain can mind: they speak of 'mass action' and favor holographic theories of memory and other mental functions. Although there is plenty of evidence for the strong coupling among a number of neural systems, there is also evidence for localization—of, e.g., pleasure and speech.

So we are left with *psychosystemism*, or the hypothesis that the brain,

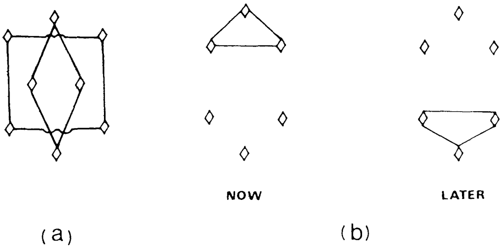

Fig. 4.1. (*a*) Two neural microsystems occupying roughly the same spatial region yet functionally detached: they 'subserve' different functions. (*b*) Psychons can be itinerant even if the components stay in place, because their connections change in time.

far from being either a heap of self-sufficient units or a homogeneous jelly, is a *system of specialized subsystems* or organs, some of which are itinerant rather than fixed. There is multiple evidence for psychosystemism, so we shall adopt it. Besides, psychosystemism accords with our systemist world view and furthermore it suggests the most fruitful research strategy, namely that of investigating the brain as a whole as well as all of its subsystems, their mutual couplings, and their links with non-neural subsystems, particularly the endocrine system.

The systemic approach to the CNS is necessary but insufficient: we must also take development and evolution into account. Dualism regards the mind as an invariable entity, holding that each person keeps his or her "personal identity" throughout life. However, the empirical evidence is against this thesis: the newborn human has hardly a mind, after a few months has learned a number of tricks, and continues to learn until senility sets in. In short the CNS of vertebrates is plastic. Moreover it has evolved from modest beginnings. The believers in the myth of the immaterial mind must ignore the evidence that the mind has evolved along with other bodily functions. So, we shall ignore the dualistic myth of personal identity: we shall hold instead that the only constant thing about John Smith is his name.

1.3. *Initial Definitions*

We start by making

DEFINITION 4.1 An *animal* is an organism that
(i) feeds on other biosystems;

(ii) can move as a whole toward or away from some stimuli;

(iii) can explore its surroundings in search of food, water, or stimulation, or to avoid stimuli that might impair its health,

We shall next define a nervous system as an information biosystem in an animal. We can and must do without the concept of information in biochemistry and in cellular biology, not however when dealing with organisms endowed with endocrine or, *a fortiori*, neuroendocrine systems. Here the environmental and the internal inputs not only are nonspecific energy transfers but sometimes also generate specific signals conveying definite information about events. Indeed there is a definite code – a naturally evolved one of course – whereby stimuli of a certain kind (e.g. thermal) are "translated" (transduced) into neural pulses in the organism; and these signals in turn activate other components, e.g. muscles or glands. These are signals proper not just neutral energy fluxes: they carry information and they trigger the release of much greater quantities of energy than they transport. The nervous system, in sum, is a genuine information network, for it detects, generates, and transmits information in accordance with definite natural codes. Hence we make

DEFINITION 4.2 A system is a *nervous system* iff it is an information biosystem (i.e. a living signal-detecting-and-processing system) such that

(i) it is composed of (living) cells;

(ii) it is or has been a proper part of a multicellular animal (i.e. the complement of the latter in the immediate environment of the system);

(iii) its structure includes (*a*) the regulation or control of some of the biofunctions of the animal, and (*b*) the detection of internal and environmental events, as well as the transmission of signals triggered by such events.

DEFINITION 4.3. A biosystem is a *neural* (or *neuronal*) system iff it is a subsystem of a nervous system.

DEFINITION 4.4. A biosystem is a *neuron* iff it is a cellular component of a neural system.

Remark 1 The vertebrate nervous system has a third structural property: it interacts directly with every other system of the animal. And the CNSs of higher vertebrates are more than information processors: they are also information generators. More on this in Sec. 4.5. *Remark 2* Neural circuits and ganglions, cell assemblies (Hebb, 1949) and neuron populations

(Freeman, 1973), working constellations (Luria, 1966) and itinerant neural systems or pexgos (Bindra, 1976) are neural systems, and so are the functional columns of cortical neurons (Mountcastle, 1957; Powell and Mountcastle, 1959; Hubel and Wiesel, 1963). *Remark 3* The neural systems capable of perceiving signals, imagining, or willing, are probably composed of millions or billions of neurons. However, even neuron systems composed of a few neurons are bound to possess properties that its components lack, i.e. emergent properties. Therefore neuronal systems are ontologically irreducible entities even if they are (up to a point) epistemically reducible, i.e. explainable in terms of composition and structure. *Remark 4* The preceding remark counters the dualistic argument that, because all cortical neurons look alike (to the untrained eye), they cannot be attributed the diversity of functions imputed to them by the monists. Actually no two neurons are alike. And even if they were, we know that they form systems (in particular, columns) – and, as any child experienced with Lego or Meccano knows, there is no end to the variety of systems that can be formed with a few elements. *Remark 5* Exclusive attention to the individual neuron and its alleged "all or none" firing pattern is misleading for it favors focusing on discontinuous processes and analogies with digital computers. Mental processes involve presumably millions of neurons and therefore continuous or quasi-continuous processes. This allows one to build continuous models of neural systems (Rashevsky, 1972; MacGregor and Lewis, 1977). And it disposes of the so-called "grain objection" to the psychoneural identity hypothesis, namely that whereas brain events are spatially and temporally discrete, we can have experience of continuous expanses of red.

The various neuronal systems differ in their mode of connection. There are several types of interneuronal and intersystem connection: constant or fixed, variable in a regular way, and variable in a random way. In order to discuss neural connectivity we had better define this notion. One way of doing it is as follows. Call $C_t(a, b)$ the strength of the connection from neuron (or neuron assembly) a to neuron (or neuron assembly) b of a given system at time t. In general, $C_t(a, b) \neq C_t(b, a)$. The $a - b$ connection is *excitatory* at t iff $C_t(a, b)$ is positive, and *inhibitory* iff $C_t(a, b)$ is negative. The excitation or inhibition caused by cell a on target cell b equals the output of a times $C_t(a, b)$. And the total input to cell b is obtained by adding all the partial inputs (i.e. by summing over a). The matrix $\|C_t(a, b)\|$ displays the total connectivity of the system at time t. The connectivity of a neural system with 1 million neurons is represented by a 1,000,000 × 1,000,000 matrix (lumping the hundreds of synapses of each cell into a single junction). Since we shall make heavy use of this concept we may as well display it for future reference:

DEFINITION 4.5. Let ν be a neural system and $\mathscr{C}_t(\nu)$ the neuronal composition of ν at time t. Further, call

$$C_t\colon \mathscr{C}_t(\nu) \times \mathscr{C}_t(\nu) \longrightarrow [-1, 1]$$

the function such that $C_t(a, b)$, for $a, b \in \mathscr{C}_t(\nu)$, is the strength (intensity) of the connection (coupling, link) from neuron a to neuron b at time t. Then the *connectivity* of ν at t is represented by the matrix formed by all the connection values, i.e.

$$\mathbb{C}_t = \|C_t(a, b)\|.$$

DEFINITION 4.6. A connectivity is *constant* iff it does not change once established (i.e. iff $\mathbb{C}_t$ is independent of time). Otherwise it is *variable*.

DEFINITION 4.7. A neuronal system is *plastic* (or *uncommitted*, or *modifiable*, or *self-organizable*) iff its connectivity is variable throughout the animal's life. Otherwise (i.e. if it is constant from birth or from a certain stage in the development of the animal), the system is *committed* (or *wired-in*, or *prewired*, or *preprogrammed*).

DEFINITION 4.8. Every plastic neural system is called a *psychon*.

So much for our preliminary definitions. We are now ready for the first bunch of axioms of our theory of the mind.

1.4. *Basic Assumptions*

Our first hypothesis is rather obvious:

POSTULATE 4.1. All animals with a nervous system have neuronal systems that are committed, and some animals have also neuronal systems that are plastic (uncommitted, self-organizable).

Apparently worms, insects and other lowly animals have only totally (or nearly totally) wired-in neuronal systems. On the other hand the plastic cortex of man is the largest in all animals and a sort of vast reserve army ready to meet emergencies, most of which never happen. Hence whereas the behavioral repertoire of lowly animals is predetermined (programmed), that of man (and many another vertebrate) can evolve in the course of his life. More on behavioral plasticity in Sec. 3.3.

POSTULATE 4.2. The neuronal systems that regulate (control) the internal milieu, as well as all the biofunctions of the newborn animal, are committed (wired-in).

Example The temperature and acidity of the intercellular fluid are regulated mainly by certain wired-in neuronal systems, and so are the breathing and sucking movements of the newborn animal. But they are not the only regulators: also the endocrine system plays an important role in internal control.

POSTULATE 4.3 The plastic (uncommitted) neuronal systems of an animal (i.e. its psychons) are coupled to form a supersystem, namely the *plastic neural supersystem* of the animal. Symbol: P.

POSTULATE 4.4 Every animal endowed with psychons (plastic neuronal systems) is capable of acquiring new biofunctions in the course of its life.

From Postulates 4.1 and 4.4 it follows that some animals are in fact capable of acquiring new biofunctions in the course of their lives. (But of course the emergence of new biofunctions is only an indicator, not a proof, of the existence of plastic neuronal systems.)

Finally we make

DEFINITION 4.9 Every neural function involving a psychon (or plastic neural system) with a regular connectivity (i.e. one that is constant or else varies regularly), is said to be *learned.*

In other words, we assume learning to consist in the formation of new neural systems, i.e. in establishing permanent connections among neurons or facilitating ephemeral (but repeatable) neuron interconnections. Some such connections may be formed accidentally (at random); if valuable, they have a chance of becoming established or of recurring. These ideas go back to Ramón y Cajal and Hebb: they proposed the use-disuse hypothesis, which has been the object of much recent experiment (e.g. Moore, 1976; Rutledge, 1976) and theory (e.g. Malsburg, 1973; Cowan, 1976).

Let us proceed to refine the above ideas with the help of the concepts of state function and state space (Ch. 1, Sec. 2.2), and to introduce the special concept of mental function.

2. BRAIN STATES

2.1 *Brain Functions*

We have defined the functions of a system as the set of processes in the system, i.e. what the system does; and the specific functions of the system as those that the system, but no thing of any other kind, is capable of doing (Ch.3, Sec. 2.2, Def. 3.8). Just as there is no system without functions (processes), so there is no function without a system that does the functioning. When a neuroscientist says that function *X* is *mediated* or *subserved* by "structure" (neuron system) *Y*, he means that *Y does X* and, more precisely, that *X* is among the specific activities or processes of *Y*,

Being a multibillion-neuron system, the mammalian CNS engages in activities of a large variety, from synthesizing proteins to controlling the functions of other organs to performing higher functions such as forming a map of the surroundings. We shall not be concerned with the nonspecific or "household" CNS functions, except to note that, if anything, they are more intense than anywhere else in the body, as judged from the rates of oxygen intake and protein turnover. We shall instead focus on the specific functions of the CNS, which may be grouped into two large classes: control and cognition.

Control can be of internal systems (e.g. digestion), of external moving parts (motor), or of sensory inflow. And cognition can be of external events, of internal activity except the brain's, or of brain activity itself – in which case it is called 'consciousness'. We know from Chapter 3 that control is inherent in every biosystem and, indeed, in every biochemical system. What is peculiar to the control functions of the CNS is that they are ultimate and integrative, i.e. that there is no appealing them and that they concern the whole organism. But we shall not be concerned with the control functions of the CNS because they are nowadays of little philosophical interest. We shall instead deal with the cognitive activities or functions of the CNS.

In the first place there is the cognition of the external world, which can be direct (perceptual) or indirect (intellectual). The former shall concern us in Sec. 3.1, the latter in Sec. 4.3. Next come the various kinds of information that the brain receives from the rest of the body, and integrates and processes. Some of them, like the visual images, are rather specific and localized; others, like elation and depression, are rather nonspecific and nonlocalized. But all of them are functionally related to further bodily events: they are signalled by physiological changes outside the brain and in turn react upon them. Finally comes the brain's cognition of some of its own states, i.e. self-consciousness. We shall deal with it in Sec. 5.1.

We proceed now to explain the state space representation of CNS activity. Consider an arbitrary neuronal system, be it a small neuronal circuit (fixed or itinerant), a sizable subsystem of the CNS, or the entire brain. Like every other system, it can be represented by a state function $\mathbb{F} = \langle F_1, F_2, \ldots, F_n \rangle$. If we are interested not in the precise localization of the system and its components, but only in its overall nonspatial properties, we can assume that $\mathbb{F}$ is only a time-dependent function whose values are n-tuples of real numbers. I.e. we can set $\mathbb{F} : T \rightarrow \mathbb{R}^n$, with $T \subseteq \mathbb{R}$, and $\mathbb{R}$ the set of real numbers. (We take the host of the neural system, i.e. the whole animal, as its reference frame.)

Each component F_i of the state function $\mathbb{F}$ can be decomposed into a constant (or nearly constant) part F_i^c and a variable part F_i^v: see Figure 4.2. Obviously, either can be zero during the period of interest. However, the point is that, while the rate of change of F_i^c vanishes at all times (i.e. $\dot{F}_i^c = 0$), that of F_i^v does not. The latter may therefore be taken to represent the activity of the neuronal system in the ith respect. For this reason we make.

DEFINITION 4.10 Let $\mathbb{F} : T \rightarrow \mathbb{R}^n$ be a state function for a neural system ν, and let $\mathbb{F} = \mathbb{F}^c + \mathbb{F}^v$, with $\dot{\mathbb{F}}^c = 0$ (zero rate of change) for all $t \in T$. Then

(i) ν is *active* at time t iff $\mathbb{F}^v(t) \neq 0$;

(ii) the *intensity of the activity* of ν over the time lapse $\tau \subset T$ equals the fraction of components of ν active during τ;

(iii) the *state of activity* of ν at time t is $s = \mathbb{F}^v(t)$;

(iv) the (total) *process* (or *function*) ν is engaged in over the time interval $\tau \subset T$ is the set of states of activity of ν:

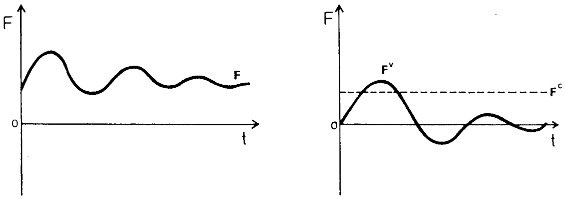

Fig. 4.2. Decomposition of a state function $\mathbb{F}$ into a constant part $\mathbb{F}^c$ and a variable part $\mathbb{F}^v$.

$$\pi(\nu, \tau) = \{\mathrm{F}^{\nu}(t) \mid t \in \tau\}.$$

Whereas single neurons may pass twice through almost the same state of activity, it is most unlikely that a neural system composed of a million neurons will do the same. We may assume that there are no two identical successive states of activity of a medium-sized neural system and, *a fortiori*, of a gross neural system such as, e.g., the hippocampus. Since mental states will be identified with some such states of activity, it follows that no mental event ever recurs in exactly the same form.

We now introduce the concept of specific activity of a neural system as a mere application (specification) of the concept of specific function of a biosystem (Definition 3.8 (ii)):

DEFINITION 4.11 Let $\pi(\nu, \tau)$ be the total process (or function) of a neural system ν in an animal b during the time interval $\tau \subset T$. The corresponding *specific function* (*activity, process*) of ν during τ is

$$\pi_s(\nu, \tau) = \pi(\nu, \tau) - \bigcup_{\mu \lessdot b} \pi(\mu, \tau) \quad \text{with} \quad \mu \neq \nu.$$

We have postulated that every thing changes spontaneously in some respects, inductively in others (Vol. 3, Postulate 5.11). In particular, neurons are never quiescent, and the human CNS is active even when sensory stimulation stops. We shall therefore adopt the hypothesis that the CNS, and every neural subsystem of it, is constantly active even in the absence of external stimuli. To formulate this principle consider m neurons synapsing on to a given neuron i. The rate of change of the latter's state of activity can be assumed to consist of an autonomous (spontaneous) part and another proportional to the signals of the afferent fibers:

$$\dot{F}_i^{\nu}(t) = A_i(t) + \sum_{j=1}^{m} C_t(j, i)\, F_j^{\nu}(t),$$

where $C_t(j, i)$ is the strength of the $j - i$ connection (cf. Definition 4.5). This system of equations is incomplete. It must be supplemented with a system of equations for the rates of change of the connectivities. A popular hypothesis is

$$C_t(i, j) = c_{ij} \cdot \exp(-\,|x|/b_{ij}),$$

where the c_{ij} and b_{ij} are real numbers, and $|x|$ the distance between the units i and j. Another interesting candidate would seem to be

$$\dot{C}_t(i, j) = c_{ij}F_i^v.$$

(For some mathematical models of the dynamics of cortical systems, see Marr (1970), Wilson and Cowan (1973) and Nass and Cooper (1975).)

However, here we are interested only in the general principle:

POSTULATE 4.5 For any neural system ν of an animal, the instantaneous state of activity of ν decomposes additively into two functions: $\mathbb{F}^v = \mathbb{A} + \mathbb{E}$, where $\mathbb{A}$ does not vanish for all $t \in T$, whereas $\mathbb{E}$ depends upon the actions of other subsystems of the animal upon ν.

DEFINTION 4.12 Let $\mathbb{F}^v = \mathbb{A} + \mathbb{E}$ be the active part of the state function of a neural system ν. Then $\mathbb{A}(t)$ is the *state of spontaneous activity* of ν at time t, and $\mathbb{E}(t)$ the *state of induced* (or *stimulated*) *activity* of ν at t.

Once we know, or pretend to know, how a neural system works, we may attempt to find out how two or more neural systems combine to form a supersystem. Suppose ν_1 and ν_2 are two neural systems of a given animal, with the same number m of neurons each. Call $\mathbb{F}_1^v$ and $\mathbb{F}_2^v$ their respective active state functions. And suppose further that the neurons in ν_1 synapse on to those of ν_2, so that ν_2 has a stimulated or induced activity in addition to its spontaneous activity. The simplest assumption is of course that the induced activity $\mathbb{E}_2$ of ν_2 depends linearly upon $\mathbb{F}_1^v$, i.e. $\mathbb{E}_2 = C \cdot \mathbb{F}_1^v$, where C is an $m \times m$ matrix representing the inter-system connectivity. This connectivity is time-dependent. We assume that it strengthens with use and weakens with disuse.

If ν_1 fails to activate ν_2, the value of C will have decreased, after one time interval, to $C(t + 1) = a\ C(t)$, with $0 < a < 1$. After k time intervals, $C(t + k) = a^k\ C(t)$, which approaches zero as time goes by. If on the other hand ν_2 is activated by ν_1, the connectivity will be strengthened in proportion to the simultaneous activity of the two neural systems. I.e. the increment in connectivity will be $\Delta C(t) = b\mathbb{F}_1^v \cdot \mathbb{F}_2^v$, where b is an $m \times m$ matrix of real numbers, some positive, others negative. Hence in general the connectivity value at time t will be

$$C(t) = a\ C(t - 1) + b\ \mathbb{F}_1^v(t) \cdot \mathbb{F}_2^v(t),$$

so that the state of activity of ν_2 at t will be represented by

$$\mathbb{F}_2^v(t) = \mathbb{A}_2(t) + aC(t - 1) \cdot \mathbb{F}_1^v(t) + b(\mathbb{F}_1^v(t) \cdot \mathbb{F}_2^v(t)) \cdot \mathbb{F}_1^v(t).$$

This is sheer speculation, though one in line with current trends in neural modeling. Its philosophical interest lies in showing that it is possible to construe mental states and events as states and events of neural systems, hence to treat them mathematically. More on this anon.

2.2. *Mental States and Processes*

Every fact experienced introspectively as mental is identical with some brain activity: this, in a nutshell, is the neurobiological or materialist hypothesis of the mind. For example, vision consists in the activity of neural systems in the visual system; learning is the formation of new neural connections; and memory is the activation of neural connections.

All mental activity is brain activity but the converse is false. For example some of the activities of the cortical component of the auditory system are mental; those of the committed or wired-in components (e.g. the ear drum and the cochlea) are not mental. Only plastic neural systems are capable of learning and they are the "seats" or "neural correlates" of the mental. More precisely, we assume that the mental is the specific function of certain plastic neuronal systems. Our assumption takes the form of

DEFINITION 4.13 Let b be an animal endowed with a plastic neural system P. Then

(i) b undergoes a *mental process* (or performs a mental function) during the time interval τ iff P has a subsystem ν such that ν is engaged in a specific process during τ;

(ii) every state (or stage) in a mental process of b is a *mental state* of b.

For example, acts of will are presumably specific activities of neuron modules in the forebrain. On the other hand hunger, thirst, fear, rage, and sexual urge are processes in subcortical systems (mainly hypothalamic and limbic), hence are nonmental according to our definition. What is a mental process is the consciousness of any such states – consciousness which is a process in some subsystem of P.

The following are immediate consequences of four previous definition:

COROLLARY 4.1. All and only animals endowed with plastic neural systems are capable of being in mental states (or undergoing mental processes).

COROLLARY 4.2 All mental disorders are neural disorders.

Consequently, the division between neurology and psychiatry, suggested by psychophysical dualism, is unreasonable.

COROLLARY 4.3 Mental functions (processes) cease with the death of the corresponding neural systems.

Examples Brain injuries, strokes, and of course death bring about the cessation of the mental functions normally discharged by the affected neural systems. Dualism does not explain such a "correlation".

COROLLARY 4.4 Mental functions (processes) cannot be directly transferred (i.e. without any physical channels) from one brain to another.

Consequently extrasensory perception is out of the question. (The Montreal magician Henry Morgan suggests that it should be renamed 'extrasensory deception'.)

We come now to the central concept in the philosophy of mind:

DEFINITION 4.14. Let P be the plastic (uncommitted) supersystem of an animal b of species K. Then

(i) the *mind* of b during the period τ is the union of all the mental processes (functions) that components of P engage in during τ:

$$m(b, \tau) = \bigcup_{x \prec P} \pi_s(x, \tau);$$

(ii) the *K-mind*, or *mind of species K*, during period τ, is the union of the minds of its members during τ:

$$M(K, \tau) = \bigcup_{x \in K} m(x, \tau).$$

Since the members of the set called 'mind' are brain functions (processes), it makes no sense to say that the brain is the physical "basis" of the mind. And since the human mind is nothing but the union of all the individual human minds, it makes no sense to speak of the collective mind of mankind as if it were an entity or even a functional system. On the other hand the mind of an individual animal does have functional unity: it is a functional system (Definition 1.9 in Ch. 1, Sec. 1.7), for every process (function) in it is lawfully related to at least one other process (function) in it. The "neural basis" of the unity of the mind, on which many philosophers have insisted, is this: the components of the plastic neural supersystem P, far from being uncoupled, form a system by Postulate 4.3. Hence

COROLLARY 4.5. The mental functions of (processes in) the plastic neural supersystem of an animal are coupled to one another, i.e. they form a functional system. (In short, for every animal b and every period τ of its existence, $m(b, \tau)$, if nonvoid, is a functional system.)

Consequently when a neurosurgeon cuts a living primate brain into two, he splits the plastic system into two, and thus also the corresponding mind of the animal. (See Corollary 4.7.)

Our last convention in this section is

DEFINITION 4.15. Let x be an object and b an animal endowed with a plastic neural system. Then

(i) x *is in the mind* of b iff x is a mental state or a mental process of b (i.e. if b has a plastic neural system engaged in a specific process containing x as a member or as a subset);

(ii) x *is in the mind*(or *is mental*) iff there is at least one animal y such that x is in the mind of y.

Remark 1 A mental state, or state of mind, such as one of persistent pain, or of perceiving a stationary thing, may be roughly constant. However, any such mental state is a state of activity of some neural system: no such activity, no mentation. In other words, mental states are more like states of motion than like static states such as the state of a gas in a rigid enclosure. *Remark 2* We have stated that mental states are neural states (or rather processes), not that every neural state has a mental "correlate". Although different mental states are different neural states (or rather processes), the converse is not true: a given mental state could be a process now in one itinerant neural system, now in another. Surely there are bound to be differences: even when doing routine sums, for all we know we may engage a different itinerant neural system each time – but we won't notice the difference introspectively (Bindra, 1976). (That is, calling N the set of neural states that happen to be mental, and M the set of mental states distinguishable introspectively, $M = N/\sim$, where $\sim$ is the relation of introspective equivalence.) *Remark 3* We have not characterized mental states independently of brain states, as dualists would like us to do. We have not done so for the following reasons: (*a*) mentalist predicates, such as 'sees red' and 'thinks hard', though indispensable, are coarse and vulgar rather than exact and scientific; (*b*) the whole point of the neurophysiological approach to mind is to get away from the ordinary knowledge approach and render mind accessible to science; (*c*) if mental events are characterized independently of brain events, then the identity theory turns out to be idle or false (Brandt and Kim, 1967). *Remark 4* The dualist claim that the mental must be nonphysical because it cannot be described with the help of physical concepts, such as those of pressure and conductivity, misses the point. Firstly, although such events as nightmares and feeling a sour taste are not describable in strictly physical terms, they are, at least in principle, describable in neurophysiological terms. Secondly, in ordinary life we may never care to describe mental states in neural terms, just as we do not care to describe such ordinary physical events as a car crash or the burning of a light bulb with the paraphernalia of physical theory. It would not be worth our while to do so; we are satisfied knowing that, if need be, such events, or some of their features, could be accounted for in scientific terms. *Remark 5 Pace* Armstrong (1968), mind and brain are not identical: there is no more brain-mind identity than there is lung-respiration identity. In our version of the so-called identity theory, the set of mental states is a subset of the states of the plastic neural system of the animal: see Figure 4.3.

2.3. *Psychosomatic Interaction*

The interactionist variety of dualism, from Descartes (1649) to Popper and Eccles (1977), holds that matter and mind, though heterogeneous and separate, act upon one another. This doctrine is untenable if only because

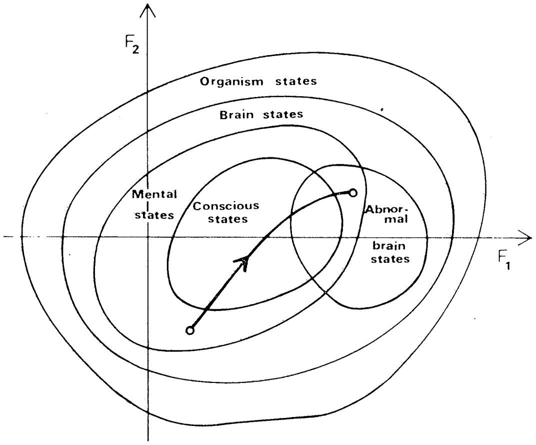

Fig. 4.3. Projection of the state space of a human being. Both axes represent neurophysiological properties; one of them is identical with a psychological property. The arc of curve represents a mental process, such as composing a melody, which is only partly conscious. One part of it is abnormal, e.g. consists of auditory hallucinations.

interactions are well defined only for concrete things (Vol. 3, Ch. 5, Def. 5.30). To speak of mind-body interaction is just as mistaken as to speak of shape-body, or property-thing, or composition-system, or behavior-animal interactions. However, it does make sense to speak of mental-bodily interactions provided this expression is taken to abbreviate "interactions among plastic (uncommitted) neural systems, on the one hand, and committed neural systems or bodily systems that are not part of the CNS, on the other". *Example* The interactions between cortical and subcortical regions of the CNS, between sensory and motor areas, between ideational neural systems and external receptors, between the visual cortex and the pituitary, etc.

Paradoxically enough, while the dualist has no right to claim that mental events influence nonmental bodily events (because he has no clear idea of such influence), the monist is entitled to this opinion. Indeed, since mental events are for him neural events of a kind, they can influence and even cause other events in any subsystem of the same body because of the integrative action of the CNS. In short, because mental events are neural events, and the causal relation is defined for pairs of events in concrete things (Vol. 3, Ch. 6, Def. 6.23), we have

COROLLARY 4.6. Mental events can cause nonmental events in the same body and conversely.

Consequently disturbances of nonmental (e.g. metabolic) biofunctions may influence mental states and, conversely, mental events, such as acts of will, may influence nonmental bodily states. This is what neurology, neurochemistry, psychiatry, education, and advertising are all about. *Example 1* Yogis learn to regulate their heartbeats, intestinal contractions and even rate of oxygen intake (cf. Miller, 1969). *Example 2* A blow in the head can "knock out the mind" erasing all memory of events immediately preceding the accident. *Example 3* By implanting electrodes in selected sites of the brain, and sending electric currents through them, the neurophysiologist can control some mental states and, through them, elicit or block behavior such as rage (cf. Delgado, 1969).

The most dramatic and revealing of all surgical interventions is of course the sectioning of the bridge between the two cerebral hemispheres, or corpus callosum (Sperry, 1964, 1966, 1977; Gazzaniga, 1967; Bogen, 1969). The split-brain patient behaves in many situations as if he were in two minds – as forecast by Fechner in 1860. For example, while his left hemisphere may wish to read, his right hemisphere may wish to go for a walk, and so a conflict arises within one and the same skull. This is not surprising in our framework: indeed, according to Postulate 4.3 and Corollary 4.4, there is a single mind as long as there is a single plastic supersystem. But if the latter is cut into two then two plastic systems emerge, each with its own mind or system of mental functions:

COROLLARY 4.7. Let b be an animal whose plastic nervous system is split into two detached parts, L and R. Then the mind of b during any time period τ posterior to the splitting divides into two disjoint functional systems:

$$m(b,\tau) = m_L(b,\tau) \cup m_R(b,\tau), \quad \text{with} \quad m_L(b,\tau) \cap m_R(b,\tau) = \varnothing.$$

Hence, *pace* Puccetti (1977), the results of commissurotomy do not support dualism. On the contrary, they show conclusively that no immaterial mind holds the hemispheres together. Dualism could be saved only by invoking divine intervention at the time of splitting the corpus callosum. God would have to replace the original single soul by two new, independent souls – each of which would have to remember something of the past history of the original soul. This looks like an easy solution but it is not for it poses the grave theological problems of which, if any, of the three souls deserves being saved, and what to do on Resurrection Day with three immortal souls and one body. Even assuming that this theological difficulty could be resolved, the dualist is in an awkward position. If he denies that the split brain patient has two minds, he defies experience. And if he acknowledges that a physical entity such as a surgeon's scalpel can slice a mind into two, he contradicts himself (Bunge and Llinás, 1978).

The chemical manipulation of the mind, though less spectacular, is no less clear cut an indictment of dualism. All drugs that act on mental states, from tea to cocaine, do so by modifying the CNS metabolism in some way or other, from changing properties of the neuron membrane to taking part in biochemical reactions. Thus by modifying membrane conduction this drug produces amnesia and that one facilitates recall; and by blocking the synthesis of a certain neurotransmitter this drug produces schizophrenia and that one cures it. (For a list of kinds of deliberate modifications of brain and behavior, see Omenn and Motulsky (1972).)

Finally, the purely behavioral or psychological manipulation of the mind is no less physical, because the sensory inflow and the behavioral output controlled by the teacher (or preacher, propagandist or psychiatrist) modulates neural connectivity, reinforcing certain connections and inhibiting others. In sum, the mental can be controlled, nay is being controlled, in various ways precisely because it is not immaterial: if it were, it would be immune to all attempts at manipulating it.

What holds for the physical control of the mind holds also, *mutatis mutandis*, for the mental control of the body, so often cited as proof of the superiority of Spirit over Matter. Consider three well known phenomena: hunger, anger, and yoga. The process involving the hunger feeling is normally this. Sensors in the digestive tract send signals to the hypothalamus, which in turn alerts the cortex. The motor cortex and the cerebellum control the muscales intervening in the search and reach for food, and in eating. The dualist thinks he can afford to skip all these links: he discards the process ensuing in the cortex's wanting the body to eat, and speaks of the direct action of the mind on the muscles. His account is far too simple – and unscientific. Saying that *X* ate because he *meant* to eat or had the *intention* of eating is just redescribing an ordinary situation in ordinary language terms, not giving an explanation of the process. And yet such accounts are as popular with ordinary language philosophers (e.g. Alston, 1974) as the account of behavior in terms of instincts was among ethologists half a century ago.

Consider anger next. The dualist is satisfied with "explanations" like this one: "She kicked him because she was angered by his words". The physiological psychologist, on the other hand, analyzes this ordinary knowledge account as a causal chain of bodily events: Hearing an utterance → Activation of psychons in the forebrain and of the adrenals → Action of forebrain and adrenals on motor center → Movement of limb. Likewise, when confronted with yoga exercises and biofeedback techniques for moving things without the intervention of any muscles, the physiological psychologist concludes that the autonomic nervous system is not as fully autonomous as we used to think, but can be subjected at least in part to control by cortical systems. There is no evidence for the action of an immaterial mind on the body and there can be no such evidence, for the ghostly is inaccessible to science. Epicurus knew this twenty-two centuries ago.

2.4. *Location of the Mind*

If the mind is immaterial then it makes no sense to ask where it is. The *prima facie* evidence for the nonspatiality of the mind is of this kind: when one thinks about something he does not feel his thoughts to be located anywhere. So much so, that in the past the heart and the liver were assumed to be the "seats" of the mind. However, as long as we remain on the ordinary knowledge level we cannot refrain from citing evidence for the thesis that the mind is coextensive with the body: e.g. when your foot hurts you feel pain there, not in your brain. So, ordinary experience is ambiguous: it supports now the thesis of the nonspatiality of the mental, now the thesis that the mind can wander throughout the body. This suggests that the nonspatiality thesis is confused, and that introspective evidence is insufficient or even irrelevant. We should examine both.

The thesis of the nonspatiality of the mental contains two different hypotheses. One is that mental events are *unextended*, the other that they occur *nowhere* – except of course "in" the mind, which is allegedly immaterial and therefore unextended. The latter hypothesis implies the former but not conversely. Indeed, mental events might be unextended yet occur somewhere – say in the brain. Likewise a physical event that takes no time occurs at some time or other. In our ontology there are no events in themselves but only events in some thing or other (Vol. 3, Ch. 5). Hence the question of the space "occupied" by an event is the problem of the extension of the changing thing. Thus not the *firing* of a neuron but the *firing neuron* is spatially extended.

Events occur wherever the "eventing" (changing) things may be (Vol. 3, Ch. 6, Sec. 4.2). In particular, mental events occur in some plastic neural system or other. So, in principle and often in practice, the neurophysiologist can locate a thought process, e.g. by eliciting it with electrical stimulation (Penfield and Rasmussen, 1950). Hence the ordinary language philosopher's claim that "it makes no sense at all" to talk about mental states and events as being located somewhere in the body has been experimentally refuted. Mental events are just as localized as the corresponding plastic neural systems. If the latter have a fixed location, so have the mental events they engage in. And if the neural system in question happens to be itinerant, the mental event itself will be itinerant – just as much as a light wave. In short, mental events occur in the brain. However, the mind, conceived of as the *set* of all mental events (Definition 4.14), is nowhere.

What about pain in limb, particularly a limb that has been amputated (phantom limb)? The short answer is that, just as we see stars in the sky, not in our brain, so we locate pains in several parts of the body, and sometimes either localization is wrong. A long answer is that the cortex of the adult human being has a map of the entire body (the somatotopic representation). It is here that the signals coming from various parts of the body are decoded and located. If they come from the stump of an amputated limb, the patient can feel them as originating in the missing part because he has formed since childhood a comparatively unalterable map. (There are alternative neurophysiological explanations of phantom experience.)

In sum, mental processes are located wherever the corresponding psychons are located; likewise they occur in time and take some time to happen. This generalization from contemporary neurophysiology – foreshadowed by the Hippocratic school – comes as no surprise for the materialist, for whom the *res cogitans* is a *res extensa*, namely the brain.

What about ideas: are they too in spacetime? The answer to this ambiguous question depends on the construal of 'idea'. If taken as ideation processes, ideas *are* in the brains that happen to think them up – and only there and at the time they are being thought. On the other hand the so called *product* of any such process, i.e. the idea in itself, is nowhere in spacetime because it does not exist by itself: we only feign it does. For example, although thinking of the number 3 is a brain process, hence one located in spacetime, the number 3 is nowhere because it is a fiction existing by convention or fiat, and this pretence does not include the property of spatiotemporality. What holds for the number 3 holds for every other idea – concept, proposition, or theory. In every case we abstract from the neurophysiological properties of the concrete ideation process and come up with a construct that, by convention, has only conceptual or ideal properties. (Cf. Vol. 1, Ch. 1.)

To sum up: Whereas the mental is in some head or other, ideas in themselves, having no being of their own, are nowhere.

2.5. *Mentalist Predicates*

At first blush the most formidable objection to psychophysical monism is this: "The materialist claims that all mental events are brain events, but he cannot offer a clear description, let alone a definition, of a mental event without the help of mentalist concepts such as those of self, privacy, and immediate accessibility. Consequently he cannot even state his identity thesis. In other words the materialist cannot consistently state the identity of phenomenal and physical predicates because he refuses to buy the former at their face value".

Actually the above is not an objection specifically addressed to the psychoneural identity thesis but one that could be raised against all science conceived of as a cognitive enterprise reaching beyond the ordinary language description of appearances. Our rejoinder is this:

(i) Science attempts to account for reality behind appearance, so it either does not employ phenomenal predicates or, if it does, regards them as derived not as basic. Surely phenomena, in particular mental phenomena, are experientially immediate, but they are neither ontologically nor scientifically primary: they are something to be explained.

(ii) Appearances (phenomena) can be explained by psychology, at least in principle, in strictly nonphenomenal terms. For example the various visual illusions can be explained either as results of incomplete or inadequate information, or as results of the fatigue of certain neurons, or the faulty connection of others.

(iii) A rigorous formulation of the monistic thesis must employ no ordinary phenomenal or mentalist predicates – or fuzzy expressions such as 'mental-neural correlation'. (At any rate ours does not.) The identity thesis is that every mental process is a brain process, not that every mentalist sentence is identical with some neurophysiological sentence: the identity is ontological not linguistic. (This important point has been obscured by the nonmaterialist version of the identity theory defended by Schlick (1925) and Feigl (1958).)

In other words, we must not demand that science descend to the level of common sense but, instead, strive to raise the latter to the level of the former. After all, this is what we do when shopping for breakfast cereal and, instead of allowing ourselves to be goaded by the advertisement that "X peps you up", we look at the protein, vitamin, and calorie content of X – or when shopping for a car and, rather than remain satisfied with the assurance that "X is spirited", we inquire into the acceleration of X. We should behave similarly with regard to mentalist predicates. More precisely, we should adopt

RULE 4.1 Whenever possible dispense with mentalist predicates: either replace them by, or define or deduce them with the help of, neurophysiological predicates.

Example of elimination "The idea of an immaterial mind controlling the body is vitalism, no more, no less; it has no place in science" (Hebb, 1974). *Example of reduction* The degree of introversion of a person equals the activity of his or her frontal-medial-septal-area hippocampal system (Gray, 1972a).

Rule 4.1 invites either of the following strategies with regard to mentalist predicates: elimination, definition, or deduction with the help of neurophysiological concepts. Of these the second, i.e. definition (or identification), has been commended by the so-called identity theorists (e.g, Smart, 1959). That is, they have proposed that, for any mentalist predicate M, there is a neurophysiological predicate N such that $M = N$, where $=$ is the relation of ordinary (or strict) identity. Ordinary language philosophers have claimed that this cannot be, for "it makes no sense" (Malcolm, 1964). The obvious rejoinder is that no scientific hypothesis whatsoever makes sense to them, for they insist on remaining within the confines of ordinary language, hence ordinary knowledge.

Another, related objection to the identity thesis, and one commended as definitive by Popper (Popper and Eccles, 1977), is as follows (Kripke, 1971). If the identity is to be taken just as seriously as "Heat is the motion of molecules", then it must be a necessary identity, in the sense that it must hold in all possible worlds – whatever these may be. However, this cannot be, because "it seems clearly possible" (to Kripke) that M (e.g. pain) could exist without the corresponding brain state N, or that the latter could exist without being felt as pain – whence the identity is contingent and therefore flimsy. Rejoinder: (*a*) scientists and science-oriented philosophers do not waste their time speculating about (logically) possible worlds: they want to explore the real world (Bunge, 1977a); (*b*) the difference between necessary (or strict) identity and contingent identity does not occur in ordinary logic or in science. In sum, the sophistic objection to materialism holds no water.

Surely our Rule 4.1 is not a summary of the state of the art but rather a programmatic injunction, i.e. one that can guide research. As such it can be confirmed. And it should be discarded (or simply forgotten) if found barren. But, far from barren, it is behind many a success in contemporary psychology and neuroscience.

Note that Rule 4.1 is the *weak* not the strong reductionist thesis: we favor the *partial* reduction (definition or deduction) of the mental to the neurophysiological, not the elimination of its emergent properties (cf. Bunge, 1977b, 1977c). Thus we do not state that a frog enjoys listening to a Beethoven quartet, or that what a human feels when listening to it is no different from a frog's sighting a fly. We only say that enjoying Beethoven is a process in a human auditory system educated to face such experience.

The partial reducibility (definability or deducibility) of mentalist predicates does not entail that *every* ordinary language sentence concerning mental events is translatable without further ado into a (possibly very complex) scientific formula. Nor, *a fortiori*, does it entail that every mentalist sentence is identical with some neurophysiological sentence. If this were so then there would be a difference only in degree between the scientific and the mythical accounts of the mental. In short, genuine psychoneural monism (unlike the linguistic "identity theory") does *not* assert that, given any mentalist sentence m, there is a neurophysiological sentence n such that $m = n$.

The best one can do with mentalist sentences is either to eliminate them altogether or to try and cleanse, deepen, and refine them. For example, the phrase 'The soul survives', which makes sense in some theologies, makes none in our framework, where *soul* does not occur at all and *mind* is defined as a set of neural processes. (Sets are neither alive nor dead.) And those ordinary language mentalist sentences that are transtatable into neurophysiologese – e.g. 'Her mind is at work', or 'I am having a yellow afterimage' – may be so only roughly. As for the converse translation, of neurophysiological and psychophysiological sentences into ordinary language (mentalist) sentences, it is, more often than not, impossible, as should be obvious from looking at any of the mathematical models of mental processes published over the past few years.

In short, the various languages employed to describe mental events – in particular mentalese, behaviorese and neurophysiologese – are not inter-translatable on the whole. This is because, save exceptions, their sentences do not express the same propositions. For example, 'She is happy', 'She is grinning', and 'Her pleasure center is active' are, though related, quite different. In fact, although they have the same referent (she), and each describes one aspect of one and the same process, they have different senses and therefore are inequivalent.

The inequivalence of most mentalist and neurobiological propositions is no obstacle to the building of bridges between them. The entire science of psychophysics is an attempt to disclose some such bridges, e.g. the relation between sound intensity and felt loudness. (Psychophysical laws are of the form: "For all x, if x is an animal of species K, then: If physical stimulus p impinges on x, then x feels mental phenomenon m". Such generalizations may eventually be deepened by expressing m in neurophysiological terms.) Neurology, too, looks for bridges between the mental (and also behavioral) states reported by neurological patients in phenomenal language (e.g. 'I suffer from migraine'), on the one hand, and sentences describing the corresponding malfunction of the CNS on the other.

(Neurological laws are of the form: "For all x, if x is human, then: If x is in neurological condition n, then x feels mental phenomenon m".)

So much for the general and basic concepts and assumptions of our version of the psychobiological theory of the mental. We proceed now to examining a few particular and rather typical kinds of mental process.

3. SENSATION TO VALUATION

3.1. *Sensing and Perceiving*

All things react to external stimuli, but some react more selectively than others: they are said to detect them. The general concept of specific reaction, or detection, is elucidated by

DEFINITION 4.16 A system *detects* things or events of a certain kind (or is a *detector* of them) if and only if it reacts to them only.

Multicellular organisms have a variety of detectors grouped into systems called *selective systems* (or also, misleadingly, *recognition systems*). For example, the immune system can detect a large variety of molecules because it is composed of detectors (antibodies) of many kinds. And the CNS can detect a huge variety of internal and external events, though by no means all of them.

For an animal it is not enough to possess detectors: the animal must be able to do something about the events it detects. This necessitates amplification and transmission of signals in a uniform fashion, so that each signal can be "read" unambiguously by the CNS. This is what neurosensors or neuroreceptors do. A mammal has myriads of neurosensors: for motion, pressure, heat, rate of secretion, acidity changes, muscle contraction, novelty, etc. This is the general concept:

DEFINITION 4.17 A detector is a *neurosensor* (or *neuroreceptor*) iff it is a neural system or is directly coupled to a neural system.

Example The visual cortices of cat and monkey (and probably also of man) contain neurons specializing in detecting vertical lines and others horizontal lines (Hubel and Wiesel, 1959, 1962). These are called *feature detectors*.

In higher animals neurosensors come in systems, so we need

DEFINITION 4.18 A *sensory system* of an animal is a subsystem of the nervous system of it, composed of neurosensors and of neural systems coupled to these.

The sensory systems of the higher vertebrates are extremely complex systems involving not only sense organs but also portions of the cerebral cortex. Moreover they are closely linked to other subsystems of the CNS, particularly the motor system. And they are not just detectors of environmental inputs, like the thermocouple or the photoelectric cell. Indeed the sensory systems are under the constant action of the CNS by way of the gamma afferent fibers, so that their state depends not only upon external stimulation but also on the state (and history) of the CNS. This explains why we seldom perceive the same stimulus in the same manner. And it shows that (*a*) stimulus-response psychology is basically false, and (*b*) any model of perception contrived in imitation of purely physical or chemical detectors, such as photographic cameras, is bound to fail.

Next comes

DEFINITION 4.19 A *sensation* (or *sensory process*, or *feeling*) is a specific state of activity (or function or process) of a sensory system.

Feeling cold or hot, hungry or sated, tired or energetic, pain or pleasure, and so on, are functions of so many sensory systems. All sensations (or feelings) are then in the brain even though they are usually elicited outside it. Hence sensations can be either blunted or made more acute by manipulating the brain, be it electrically, chemically, or behaviorally. If they were in an immaterial mind we would have no access to them from the outside.

Sensing is not all: in vertebrates sensory information is processed or "interpreted" by special sensory "areas" in the brain cortex. In the primate brain each such sensory cortical "area" can be subdivided into three parts: the primary, the secondary, and the tertiary ones. Only the primary sensory cortical area should be regarded as a component of the corresponding sensory system. Presumably it loses plasticity as the animal develops. On the other hand the secondary and tertiary sensory areas seem to be plastic throughout the animal's life. We shall call them the *plastic* neural systems *directly* attached to the sensory system. We shall assume with Hebb (1968) that, whereas sensation is the specific activity of a sensory system including the primary sensory cortical area, perception is this activity together with the activity elicited by the sensory system in the plastic neural system directly attached to it. See Figure 4.4.

This figure summarizes the following features of human perception:

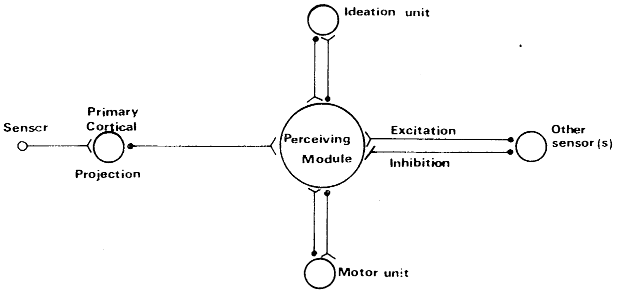

Fig. 4.4. Schema of a perceptual system: a modification of Bindra's (1976), in turn a modification of Hebb's (1949).

(i) the perceiving is done by a neural system located in a secondary sensory projection of the brain cortex;

(ii) the functioning of the central perceiving unit is strongly influenced by some motor unit or other as well as by ideational units and by sensory inflows of various modalities;

(iii) the central perceiving unit can be activated by any other units coupled to it (e.g. dreams, hallucinations, phantom limb experiences, eidetic images);

(iv) perception can guide motion as well as ideation.

We compress the preceding into

DEFINITION 4.20 (i) A *percept* (or *perceptual process*) is a specific function (activity, process) of a sensory system and of the plastic neural systems(s) directly coupled to it;

(ii) a *perceptual system* is a neural system that can undergo perceptual processes.

We assume – in line with Bindra (1976) – that, whereas a sensory system has a roughly constant neuronal composition, the corresponding perceptual system has a variable part. This explains why a given stimulus can activate different perceptions (as in the case of the duck-rabbit figure or of the Necker cube) and why different stimuli can give rise to the same perception (as in the case of size constancy). See Figure 4.5. In other words, two percepts are *equivalent* iff they are elicited by the same sensation and involve the same plastic neural system.

We shall assume that the perception of an external object is the distor-

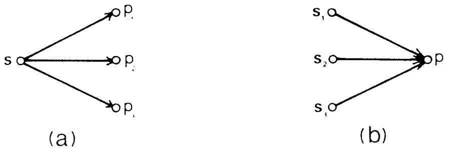

Fig. 4.5. Sensation and perception. (*a*) Same sensation elicits different perceptions according to the plastic neural assembly it activates. (*b*) Different sensations give rise to same perception by activating the same plastic neural system.

tion it causes on the ongoing activity of a perceptual system. To be more precise, we assume

POSTULATE 4.6 Let ν be a perceptual system of an animal b, and call $\pi_s(\nu, \tau) = \{\mathbb{F}^{\nu}(t) \mid t \in \tau\}$ the specific process (or function) that ν engages in during the period τ when in the presence of a thing x external to ν, and call $\pi_s^{\circ}(\nu, \tau)$ the specific function of ν during the same length of time when x fails to act on ν. Then b perceives x as the symmetric difference between the two processes. I.e. the perception of x by b during τ is the process

$$p(x, \tau) = \pi_s(\nu, \tau) \Delta \pi_s^{\circ}(\nu, \tau).$$

This postulate accounts for the active or creative nature of perception and thus for the fact that one and the same perceptual system, when in different states, will perceive differently a given object. This hypothesis disagrees with the direct apprehension doctrine of empiricists and intuitionists (in particular Gestalt theorists). But it is consonant with the current neurophysiology of perception, particularly because it incorporates the spontaneity of the CNS denied by the causal theory of perception. External and internal stimuli do not set the CNS in motion but modulate or control its incessant activity. I.e. the environment enhances or dampens, and in general controls or modulates the activity of the CNS rather than causing it.

3.2. *Mapping Body and Environment*

What do we perceive and how? The naive realist's answer is: We perceive things as they are. Yet imagine Parmenides' homogeneous and eventless universe. An observer would be unable to perceive anything in it, because there would be nothing to discriminate from anything else, and because nothing would be stirring. He would be unable to see, because only things that bounce photons back can be seen; he would hear nothing, because only moving things can generate sound waves; and he would have no tactile sensations, because touching is disturbing – and being disturbed. The observer himself must be changeable, because perception is a process in an animal equipped with perceptual systems.

So, we perceive not things but events, and not all events but only some of those that affect us: the light bouncing off the surface of the lake and hitting our retina, the cry of the owl flying nearby and generating sound waves that set our ear drums in motion, the flame licking our hand, and so on. Whatever we perceive is an event or a sequence of events, and not just any event but one originating in a neurosensor or acting on the latter and, in any case, belonging to our own event space (or the set of events occurring in us). And our perceptions are in turn events in the plastic part of our own sensory cortex. They are not autonomous events but events that map or represent events occurring in other parts of the body or in our environment. Surely this mapping is anything but simple and faithful, but it is a mapping nevertheless. Thus we assume

POSTULATE 4.7 Let b be an animal equipped with a perceptual system c, and call $S(b)$ the state space of b, and $S(c)$ that of c. Moreover, let $E(b) \subset S(b) \times S(b)$ be the animal's event space, and $E(c) \subset S(c) \times S(c)$ its perceptual event space. Then there is a set of injections (one to one and into functions) from the set of bodily events in b to the set of perceptual events in c. Each map, called a *body schema*, depends on the kind of bodily events as well as on the state the animal is in. I.e. the general form of each body map is

$$m: S(b) \times 2^{E(b)} \longrightarrow 2^{E(c)},$$

where 2^X is the family of all subsets of X.

Remark 1 This assumption does not specify the body schemata and does not even state how many there are. Such specifications are tasks for psychobiology. *Remark 2* At first blush phantom limb experiences refute the postulate. They do not, because the body schemata are learned: young children do not have that experience. *Remark 3* The bodily events $x \in 2^{E(b)}$ can be said to be felt by animal b in state s iff b has a body schema m such that $m(s, x) \in 2^{E(c)}$ – i.e. if those events project on to the cortex c of b.

The external world maps are similar to the body schemata. Only, in this case the bodily events are caused by external events, and the maps are far more numerous than the body schemata. In fact there is an entire atlas of the external world, made up of dozens of maps – one for shapes, another for colors, another for motion, and so on. Our assumption is

POSTULATE 4.8 Let $E(e)$ be a set of events in the environment e of an animal b equipped with a perceptual system c, and call $S(b)$ the state space of b and $S(c)$ that of c. Moreover let $E(b) \subset S(b) \times S(b)$ be the animal's event space, and $E(c) \subset S(c) \times S(c)$ its perceptual event space. Then there is a set of partial maps k from sets of external events in $E(e)$ to ordered pairs $\langle$state of b, set of bodily events in $b\rangle$, and another set of partial maps p, from the latter set to sets of perceptual events. Furthermore the two sets of maps are equally numerous, and each map k composes with one map p to form an *external world map* of b in e, or ε. I.e.

$$\varepsilon: 2^{E(e)} \xrightarrow{k} S(b) \times 2^{E(b)} \xrightarrow{p} 2^{E(c)}.$$

DEFINITION 4.21 Let b be an animal with perceptual system c in environment e. Moreover call $S(b)$ the state space of b and $E(e)$ that of e. Then b, when in state $s \in S(b)$, *perceives* external events in $x \in 2^{E(e)}$ if and only if [these cause bodily events that are in turn projected on to the sensory cortex c, i.e. if] $k(x) = \langle s, y\rangle$ with $y \in 2^{E(b)}$ and in turn $p(s, y) \in 2^{E(c)}$. Otherwise the events in x are *imperceptible* to b when in state s [i.e. imperceptible events either do not cause any bodily events or cause them but do not get projected on to the perceptual system].

Remark 1 Just like the body schemata, the external world maps are not point to point but rather set to set correspondences. *Remark 2* There are many external world maps, several for each modality. The various visual maps integrate into one, which constitutes the visual space. Likewise the auditory maps integrate into the auditory space, and so on. *Remark 3* The various sets of external world maps, one for each modality, integrate in turn into the external world atlas. This integration can be explained as the simultaneous activation of the various perceptual systems. Such an activation can be achieved by sensory inflow to one or more receptors, and activation of other perceptual systems via associated neural systems. For example, a total or crossmodal perception of a familiar hand may be had just by its haptic perception, because the tactual receptors activate others. Such integration is learned. *Remark 4* Not only does the organism learn to integrate the activities of its various perceptual systems: it also learns to perceive in each modality. In particular, the young vertebrate learns to touch, to hear, to see, and to smell. Here again the psychobiological viewpoint can teach us something that dualism cannot. In fact from a neurobiological point of view learning to perceive is a process of self-organization of the synaptic junctions in the sensory cortex.

3.3 *Behavior: Definitions and Principles*

The set of motor outputs of an animal, whether global as in locomotion or partial as in grasping or grinning, moving the eyeballs or excreting, is called its behavior. In short, we make

DEFINITION 4.22 For any animal b,

(i) the *behavioral state* of b at time t is the state of motion of b at t;

(ii) the *behavior* of b during the time interval τ is the set of all behavioral states of b throughout τ.

When inherited, or else when learned and successful, behavior can become stable or recurrent. In this case it is often called a behavior pattern:

DEFINITION 4.23 A *behavior pattern* is recurrent behavior.

Animals belonging to different species can do different things, such as swimming of flying, burrowing or building nests, preying or fleeing from predators. And even when they do the same 'thing' (i.e. go through the same motions) they may do so in different fashions or styles. In short there are different kinds of behavior, and every animal species is characterized by some to the exclusion of others. We need then

DEFINITION 4.24 Let b be an animal of species K, and let A be the union of all animal species. Then

(i) the (*possible*) *behavior of type i of animal b*, or $B_i(b)$ for short, is the set of all (possible) behaviors of b associated with the ith biofunction (in particular neural biofunction) of b;

(ii) the *behavioral repertoire* of animal b, or $B(b)$ for short, is the union of all (possible) behavior types of b, i.e.

$$B(b) = \bigcup_{i=1}^{n} B_i(b);$$

(iii) the (*possible*) *behavior of type i of species K*, or $B_i(K)$ for short, is the union of all the (possible) behaviors of the members of K, i.e.

$$B_i(K) = \bigcup_{x \in K} B_i(x);$$

(iv) the *behavioral repertoire of species K*, or $B(K)$, is the union of all (possible) behavior types of K:

$$B(K) = \bigcup_{i=1}^{n} B_i(K);$$

(v) the *specific behavioral repertoire of species K* is the behavioral repertoire exclusive to members of K:

$$B_s(K) = B(K) - \bigcup_{X \subset A} B(X), \quad \text{with} \quad X \neq K;$$

(vi) *animal behavior* is the union of the behavioral repertoires of all animal species, i.e.

$$B = \bigcup_{X \subset A} B(X).$$

(All of the above definitions are understood to refer to a given stage in the development of the individual or the evolution of the species. As an animal develops its behavioral repertoire changes. Something similar holds for the evolution of behavior.)

Our first assumption is that behavior, far from being primary, is derivative:

POSTULATE 4.9 The behavior of every animal endowed with a nervous system is controlled ("mediated", "subserved") by the latter. I.e. for every behavior type B_i of animals endowed with a nervous system, the latter contains a neural subsystem that controls the motions in B_i.

An immediate consequence is

COROLLARY 4.8 Any change in (nonredundant) neural systems is followed by some behavioral changes.

Now, there are no two identical nervous systems – nor, for that matter, two physical systems identical in all respects. This generalization, together with Postulate 4.9, entails

THEOREM 4.1. No two animals behave in exactly the same way [even if they are conspecific].

The assumption that a nervous system may contain a plastic subsystem (Postulate 4.1), together with Postulate 4.9 and Definition 4.24, entails

THEOREM 4.2. The behavioral repertoire of an animal endowed with plastic neural systems splits into two parts: the one controlled by the committed (or prewired) part of the NS of the animal, and its complement, i.e. the behaviors controlled by the plastic components of the NS.

DEFINITION 4.25. The part of the behavioral repertoire of an animal, that is controlled by the committed part of its NS, is called its *inherited* (or *instinctive, stereotyped, modal* or *rigid*) repertoire, while the one controlled by the plastic part of its NS, its *learned* repertoire.

Remark 1 'Inherited' is not the same as 'inborn'. Only the adult animal is in possession of its full inherited behavioral repertoire. (That is, *Inborn* $\subset$ *Inherited* $\subset$ *Total.*) This distinction was not adopted by Chomsky (1968) when claiming that universal grammar is an "innate schematism".
Remark 2 Because natural selection eliminates most types of behavior resulting in backfiring, instinctive or programmed behavior looks marvelously suited to goals, i.e. purposeful. But, as Spinoza (1677, First Part, Appendix) saw, this is sheer anthropomorphism, and contemporary biologists and psychologists are finding less and less use for final causes in explaining behavior.

An immediate consequence of Theorem 4.2 and Definition 4.25 is

COROLLARY 4.9. The behavior of an animal deprived of plastic neural systems is totally stereotyped.

Most inherited behavior has been selected because it is adapted to a certain environment, i.e. it is biovaluable in it. (Not all: recall the moth's compulsion to circle about a flame.) But if the environment were to change radically, some of the behavior types, formerly adaptive, would be devalued. Joining both statements we have another axiom:

POSTULATE 4.10 Provided the environment does not change radically during the lifetime of an animal, most of its inherited behavioral repertoire has a positive biovalue for it.

The great biovalue of possessing a nervous system with plastic neural subsystems is, of course, its capacity to learn new behavior types and thus improve its chances of surviving environmental changes. So, we make

POSTULATE 4.11 Some of the inherited capabilities of an animal endowed with plastic neural systems are modifiable by learning.

So much for our behavioral principles. Now for drives. Explanations of the type "X eats (or sleeps, or mates) because X has an urge (or drive) to eat (or sleep, or mate)" are not illuminating as long as the drive concept remains an occult hypothetical construct. They become genuine explanations the moment drives are construed in physiological terms, e.g. as detection of imbalances (deficits or superavits) of certain physiological variables such as sugar or noradrenalin levels in the blood. In this case the hypothesis that behavior X is caused by drive Y can be put to the test, namely by manipulating the imbalance and watching behavior changes. The entire drive theory can be compressed into one definition and one assumption:

DEFINITION 4.26. A *drive* (or *motivation*) of kind X is detection of an imbalance in the X component(s) of the state function of the animal. More precisely: the intensity $D_X(b, t)$ of drive X in animal b at time t equals the absolute value of the difference between the detected and the normal values of X for b at t.

POSTULATE 4.12. For every drive in an animal there is a type of behavior of the animal that reduces that drive (i.e. that decreases the imbalance in the corresponding property).

The adoption of this hypothesis allows one to explain many behavior patterns without resorting to teleology. Thus a bird engaged in nest building exhibits inner-driven behavior (and, more precisely, a behavior driven by neuroendocrine imbalances), The animal does not allow random sensory stimuli to divert it from its job. (For other examples of the physiological approach to motivation, see Gross and Zeigler (Eds.) (1969).)

In Ch. 3 we stated that certain states and events are objectively valuable to the organism whereas others are not. We now go a step further and affirm that all animals are equipped with receptors enabling them to evaluate some incoming stimuli as nocent, favorable, or indifferent. This does not entail that all evaluations are correct, let alone that all animals are conscious of such evaluations and can make value judgments. Only a few higher mammals can form value judgments: in all others, and even in man most of the time, valuations are automatic. What distinguishes man from other animals, with regard to valuation, is that he can reason about values as well as evaluate reasons. Other animals do not have the proper CNS for performing such syntheses of reason and value: they behave without weighing behavior and, if they reason at all, they do not weigh reasonings.

In any case, saying that an animal is capable of evaluating items of a certain kind amounts to saying that it has a value system – a concept characterized by

DEFINITION 4.27. Let S be a set of items and b an animal. Further, let $\succsim_b$ be a partial order on S. Then the structure $\mathscr{V}_b = \langle S, \succsim_b \rangle$ is a *value system* for b at a given time iff

(i) b can detect any member of S and discriminate it from all other items in S;

(ii) for any two members x and y of S, b either prefers x to $y (x \succsim_b y)$ or conversely $(y \succsim_b x)$ or both $(x \sim_b y)$ at the given time.

Remark 1 This is a comparative concept of value. A quantitative concept is that elucidated by utility theory and occurring in decision theory. *Remark 2* Note the difference between the concept of psychovalue elucidated by Definition 4.27 and that of biovalue introduced in Ch. 3, Sec.2.2. The biovalue of a for b at t is the objective value that a *possesses* for b at t. On the other hand the psychovalue of a for b at t is the value that b *assigns* to a at t. These value assignments may be biologically mistaken, in which case psychovalues conflict with biovalues. The psychophysical dualist would regard this as a conflict between mind and body, while the monist would regard it as a conflict between the brain or a subsystem of it, on the one hand, and the rest of the body or a different brain subsystem, on the other. In any case, since such conflicts do occur, we had better not try to reduce one kind of value to the other even though both valuations are biological processes. *Remark 3* Value systems are known to change for one and the same organism, not only in the course of its development but also with circumstances. Therefore we incorporate this fact into our hypothesis:

POSTULATE 4.13. All animals are equipped with a value system, and those capable of learning can modify their value systems.

Finally we introduce the notion of choice. An animal presented with a set of alternatives may abstain from choosing among them or may pick one of them. If it tries out some of the options and finds out the hard way which lead to the most valuable outcomes, the animal will be said to have learned to choose. But in all cases there must be some freedom in order for there to be genuine choice. I.e. the animal must be able to choose any of the alternatives open to it, and some choices must be (at least initially) mistaken (i.e. disvaluable) for there to be choice learning. Hence we make

DEFINITION 4.28 Let $\mathscr{V}_b = \langle S, \succsim_b \rangle$ be a value system for an animal b at a given time, and call $A \subset S$ a set of alternatives open to b, i.e. belonging to the behavioral repertoire of b at the time. Then b *chooses* (or *selects*) option $x \in A$ iff

(i) it is possible for b to pick (i.e. to do) any alternative in A(i.e. b is free to choose);

(ii) b prefers x to any other options in A; and

(iii) b actually picks (i.e. does) x.

Note the difference between preference and choice: the former underlies and motivates the latter. Choice is valuation in action, or overt valuation – hence an indicator of valuation not a definition of the latter. And note also that not every choice implements a decision. Decisions are deliberate or reasoned (even if not always rational), and reasoning is the privilege of only a few animal species. Most choices, even in daily human life, are not preceded by any decision-making process.

4. RECALL TO KNOWLEDGE

4.1. *Memory and Learning*

Many a complex prebiotic system, such as a sword and a magnet, has memory of some past states. If only for this reason we must treat memory separately from, and even prior to, learning. A general definition is

DEFINITION 4.29 A system σ at time t has *memory of* (or *memorizes*) some of its past states iff the state of σ at t is a function(al) of those past states.

A system with memory can be called a *memory system*. A memory system records ("commits to memory"), stores, and recalls when suitably stimulated. (Actually the second property may be nonexisting: instead of keeping a record, trace or engram of a state, a system may acquire just the disposition or propensity of recalling the state.) All organisms are memory systems, if only because they have genes, and these record part of the history of the species. Besides genetic memory, all organisms have at least some sort of short span memory: otherwise they would not live long enough to reproduce. So, we can assume

POSTULATE 4.14 All animals have memory of some of their past states, and none of all of them.

There is probably a large variety of memory systems or mechanisms.

We may class them into fixed and itinerant. While invertebrates and lower vertebrates have probably only fixed memory systems (i.e. systems with constant neuronal composition), higher vertebrates have also itinerant memory systems, i.e. systems that are formed just for the occasion. The latter are particularly interesting in the case of man, where remembering seems to consist not in the reactivation of some fixed neural circuit but "in the fresh production or reconstruction of an item" (Bindra, 1976, p. 330). In any case, memorizing is not passive recording but a kind of activity of certain neural systems possibly involving the strengthening of synaptic connectivities (Anderson, 1972, 1973). Nor do we "store" past events in our memory, let alone in our mind: if we store anything at all it is in our brain.

Some memory systems have the ability to learn. According to Definition 4.9, learning is the acquisition of new neural functions, whence it involves plastic (not only wired-in) neural systems. This definition differs from the usual behavioral definition of learning as modification of behavior in response to stimulation. The behaviorist definition is concerned with the effects rather than the causes, and it could be applied to any thing, for any thing will behave differently if stimulated differently.

To emphasize the idea that learning is a modification of neural activity, we make

DEFINITION 4.30 Call E a kind of event or process in a neural system of an animal a involving a plastic subsystem, and S a kind of stimuli (external or internal) which a can detect. Then a has *learned* $e \in E$ in the presence of $s \in S$ during the time interval $[t_1, t_2]$ iff

(i) e did not occur in a in the presence of s before t_1;

(ii) after t_2, e occurs in a whenever a senses s [i.e. a has memorized e].

Since all behavior is controlled by some neural system (Postulate 4.9), the previous definition embraces the concept of behavioral learning, i.e. learning to perform a movement.

We shall also adopt

DEFINITION 4.31 The *experience* of an animal at a given time is the set of all it has learned up until that time.

That is, the experience of an animal is its accumulated learning, i.e. the collection of changes in its plastic neural systems. These include of course nonperceptual learning. On the other hand "learning" to avoid harmful stimuli is not learning proper according to our definition, for it may well consist in a process involving no plastic neural systems – as is indeed the case with invertebrates. The same holds for habituation, which consists in the weakening of existing (wired-in) synaptic connections with repeated stimulation.

Learning, even of the simplest task, is creative for it consists in the appearance of new neural connections and therefore new neural functions. An animal in the process of learning expands its neural state space. This expansion can be either quantitative (i.e. keeping the same axes) or qualitative (changing some axes). A baby's forming its first sentence is presumably an example of the latter type of expansion, whereas its adding one more word to its verbal repertoire is an instance of the former. In general, discovering and inventing are of the second kind, and only a few higher vertebrates seem capable of it.

4.2. *Expectation and Purpose*

So far we have dealt only with non-anticipatory systems, i.e. systems whose behavior does not depend on the expected outcome of their actions. We now introduce anticipation, a property only animals of some species have, namely those capable of expecting either reward or punishment when presented with certain stimuli or engaging in certain activities. We first adopt

DEFINITION 4.32 Animal *b* *expects* (or *foresees*) a future event of kind *E* when sensing an (external or internal) stimulus *s* while in state *t*, iff *b* has learned to pair *s* and *t* with an event of kind *E*.

Because foresight depends upon learning, the lower animals, which have no learning ability, have no expectations either. But if an animal can learn, then it does have expectations, and in turn expecting helps (motivates) learning. Animals capable of expecting can regulate the effort they put in doing something.

It seems that all vertebrates have organs serving an anticipatory or preparatory function. Examples: the salivary glands secrete saliva at the sight of food, and the glucoreceptor cells in the intestine signal to the pancreas the intake of glucose, which stimulates it to release insulin. In both cases one subsystem alerts another, and the anticipatory functions are autonomous or nearly so. No wonder that the mammalian brain too has anticipatory functions and more refined ones: they enable some animals to foresee and to prepare themselves for what may come. These animals are said to behave in a goal-seeking or purposive way. Because expectation presupposes learning, only learned behavior can be purposive and, being learned, it is also motivated: the outcome of the purposive action is expected to bring a reduction in drive. In sum, we make

DEFINITION 4.33 An action X of an animal b has the *purpose* or goal Y iff

(i) b may choose not to do X;

(ii) b has learned that doing X brings about, or increases the chances of attaining, Y;

(iii) b expects the possible occurrence of Y upon doing X;

(iv) b values Y.

Notice the conditions for purposiveness: freedom, learning, expectation, and valuation. Obviously machines, no matter how sophisticated, do not fulfill all four conditions, hence cannot be goal-seeking – except of course by proxy. Most animal behavior is non-purposive: it only looks goal-seeking because it is so often efficient, but this efficiency is the result of control mechanisms that work without the intervention of any plastic neural systems, hence without learning or expectation.

The claim that purposes defy scientific explanation and call for the hypothesis of an immaterial mind was downed by cyberneticians, who suggested a precise general mechanism of purposive action, namely the negative feedback loop (Rosenblueth *et al.* 1943, 1950). Since then neural modellers and physiological psychologists have been able to explain some specific purposive behavior patterns. According to such models purposes are not states or entities in the mind but certain patterns of neural activity. This view, rather than the mentalistic conception of purpose, agrees with evolutionary biology, which is concerned with explaining the emergence of goal-seeking behavior as a latecomer that has nothing to do with immaterial entities.

Having defined the notion of a goal we can now define that of a means:

DEFINITION 4.34 An action X of an animal b is a *suitable means* for attaining a goal Y of b iff in fact b's performing X brings about, or increases the probability of occurrence of, Y.

4.3. *Thinking*

Forming concepts, propositions, problems, and directions are examples of thinking; so are comparing and transforming concepts, propositions, problems, and directions. We assume that thinking of any kind is an activity of some plastic neural system and, as such, one sensitive to minute chemical changes and changes in basic properties of neurons, such as membrane permeability. For example, humans unable to oxydize the amino acid phenylalanine cannot think at all, and normal subjects cannot think straight when in states of extreme stress – which are often states of hormonal imbalance – or when under the action of psychotropic drugs. Believers in the immateriality of reason must ignore the mounting evidence for the hypothesis that the content and level of performance of thinking depend upon such chemical and physiological variables – and, of course, to be consistent they must never resort to such stimulants as caffeine, nicotine and ethyl alcohol.

We shall deal here only with two basic thought processes, namely concept attainment and proposition formation. We shall conceive of the former as the process of forming kinds, such as the class of cats or that of triangles. And we shall conjecture that forming a concept of the "concrete" kind – i.e. a class of real things or events – consists in responding uniformly to any and only members of the given class. Thus we adopt

POSTULATE 4.15 Let C be a set of (simultaneous or successive) things or events. There are animals equipped with psychons whose activity is caused or triggered, directly or indirectly, by any member of C, and is independent of what particular member activates them.

DEFINITION 4.35 Let C be a class of things or events, and b an animal satisfying Postulate 4.15, i.e. possessing a psychon that can be activated uniformly by any and only a member of C. Then *b attains a concept $\theta_b(C)$* of C (or *conceives* C, or *thinks up* C) iff the activity (process, function) stimulated by a C in that psychon of b equals $\theta_b(C)$.

Consider next the formation of propositions. We conjecture that the operation involved is that of psychon pairing. For example, "Children are helpless" pairs "Children" off to "are helpless". Two psychons, possibly cortical columns, are activated sequentially, one for each concept. The sequential activity of the two component system constitutes thinking the corresponding proposition. The idea is encapsulated in

POSTULATE 4.16 Thinking up a proposition is (identical with) the sequential activation of the psychons whose activities are the concepts occurring in the proposition in the given order.

POSTULATE 4.17 A sequence of thoughts about propositions is (identical with) the sequential activation of the psychons whose activities are the propositions in the sequence,

This holds for complex propositions (such as conjunctions) as well as for "trains of thought", in particular inferences. *A fortiori*, it holds for rational thinking, or thought controlled by certain master thoughts, or rules, such as "Abhor contradiction", "Check what follows", and "Supply evidence or counterexample".

In line with our semantics (Vols. 1 and 2) we have distinguished constructs (such as concepts and propositions) from thoughts about them as well as from linguistic expressions. Unlike constructs, thoughts are brain processes. Therefore no two thoughts can be exactly identical. Nobody thinks twice of the number 5, or of the Moon, in exactly the same manner, if only because we never go through exactly the same states. However, we can assume that all the processes of thinking of the number 5 (or of any other construct) fit the same neural pattern, i.e. are equivalent in an essential respect. This notion is elucidated by

DEFINTION 4.36 Two thoughts are *equivalent* iff they consist in thinking of the same constructs. I.e.

$$\theta_a(C) \sim \theta_b(C') \quad \text{iff} \quad C = C' \text{ for any animals } a \text{ and } b.$$

It would have been desirable to define a construct as a set of equivalent neural events instead of presupposing the concept of a construct, for it would root constructs on neural events while preserving their abstract quality. Unfortunately we have been unable to find the proper equivalence relation that would allow one to construct such a definition.

4.4. *Cognition and Decision*

All cognition is of some object, concrete or conceptual, and it consists in some information about its object – complete or partial, true or false. Cognition can be behavioral (e.g. knowing how to ski), perceptual (e.g. knowing the song of the lark), or conceptual (e.g knowing that the lark song is related to its reproductive cycle or its territorial defense). If behavioral, cognition is a disposition of the motor control system to steer motions of a certain kind; if perceptual it is a potential net of percepts, and if conceptual a potential system of concepts. In either case cognition is a brain process. We summarize the preceding in

DEFINTION 4.37 Let a be an animal. Then

(i) if b is a learned behavior type (or pattern), *a knows how to do* (or perform) b iff b is in the actual behavioral repertoire of a;

(ii) if c is a construct, then *a knows c* iff a thinks up (or conceives) c;

(iii) if e is an event, then *a has knowledge of e* iff a feels or perceives e, or thinks of e.

We can use the concept of knowledge to elucidate that of decision:

DEFINITION 4.38 Let x be an arbitrary member of a set A of alternatives accessible to an animal b with the value system $\mathscr{V}_b = \langle S, \succsim_b \rangle$. Then b *decides to choose x* iff

(i) b has knowledge of every member of A;

(ii) $A \subseteq S$ (i.e. b prefers some members of A to others);

(iii) b in fact chooses x.

A possible decision mechanism is this. If the animal perceives or thinks of a number of objects, and is motivated to choose among them, then he will first compare them. Presumably each object will be apprehended by one psychon at a time, and the excitation levels of the various psychons will differ. If one of them is greater than the others, that one will prevail and will send the strongest (or the only) signal to a volition psychon.

The ability to make decisions is restricted to animals capable of knowing. But not all knowledge is of the same grade, nor all valuation correct. When they are, they constitute the basis of rational decision:

DEFINITION 4.39 A decision made by an animal is *rational* iff it is preceded by

(i) adequate knowledge and correct valuations, and

(ii) foresight of the possible outcomes of the corresponding action.

DEFINITION 4.40 A *rational animal* is one capable of making some rational decisions.

It is quite possible that rational decisions are not the exclusive property of man: some subhuman primates seem capable of making rational decisions. And it is sure that no animal is rational all the time.

4.5. *Creativity*

All higher vertebrates are creative, and man is so superlatively. This may be conceded while at the same time it is doubted whether the notion of creativity is clear. The notion is clear if construed as *neural novelty*, i.e. emergence of new neural systems or new functions of existing neural systems – due e.g. to new connections. Such neural novelties may or may not have behavioral manifestations. If they do one speaks of *adaptive behavior*, in particular imitation and invention, according as the novelty is in the particular animal or in the entire species; otherwise one speaks of mental creativity. So, we make

DEFINITION 4.41 Let a be an animal of species K with behavioral repertoire $B(K)$ at time t. Then

(i) *a invents* behavior type (or pattern) b at time $t' > t$ iff a does b for the first time, and b did not belong to $B(K)$ until t';

(ii) *a invents* construct c at time $t' > t$ iff a knows c for the first time at time t', and no other animal of the same species knew c before t';

(iii) *a discovers* event e at time $t' > t$ iff a has knowledge of e for the first time at time t', and no other animal of the same species had such knowledge before t';

(iv) a is *creative* iff a invents a behavior type or a construct, or discovers an event before any other member of its species;

(v) a is *absolutely creative* iff a creates something before any other animal of any species.

Now the hypothesis:

POSTULATE 4.18 Every creative act is the activity, or an effect of the activity, of newly formed neural systems.

Although creativity is maximal in humans, it is likely to be found among all mammals and birds – if only the theological and empiricist prejudice against the concept of creativity is overcome and the phenomenon is investigated scientifically, particularly among young animals placed in unusual circumstances. We make bold and assume that all higher vertebrates are creative:

POSTULATE 4.19 All animals endowed with plastic neural systems are creative.

However, so far as we know only humans are absolutely creative, i.e. capable of inventing or discovering certain "things" before any other animals. We shall use this assumption in defining humanness in Sec. 5.

What is the ontological status of the so-called creations of the human mind? To obtain a sensible answer we must first distinguish the creative process – whether in science, technology, art, or any other field – from its public materializations, such as books, artworks, and machines. Every creative process is a process in some brain or other (Postulate 4.18). In a few cases such mental processes are externalized as physical things or processes which, when perceived by competent observers, elicit in their own brains processes similar to those undergone by the creators. Thus a musical piece can be whistled, performed on a musical instrument, listened to, written down or read. Novels and theories, artifacts and constitutions are similar. What becomes of a musical piece between performances or listening sessions, or after everybody has forgotten it? It does not exist. If the memories of the piece have faded in all brains, and if all scores and discs have been destroyed, the music itself is no more and has no chance of resurrection – except for the most unlikely chance of being reinvented. But if some traces of it do remain – either in brains or on paper, discs or tapes – then the musical piece has the possibility of "coming alive" again. Something that cannot be played on an instrument, an audio system or something similar, and cannot even be hummed, is not a musical piece.

I submit that the same holds, *mutatis mutandis*, for all cultural objects. Thus a sculpture that nobody looks at is just a chunk of matter – and so is a philosophical treatise that nobody reads. There is no immortality in cultural creations just because they can be externalized ("embodied") and catalogued. Only that endures which is being recreated – reperceived, refelt, rethought, re-enacted. Deserted libraries, museums, art galleries, and laboratories, are just cultural cemeteries. Nothing is more dependent and vulnerable – less autonomous – than the "world" of culture. (Let the current contempt for basic science prevail, and soon there will be no scientific culture left.) Culture lives neither in cultural artifacts, such as books, nor in an immaterial and autonomous world of ghosts: it lives in the brains of those who care about it – who cultivate it.

Ideas, then, do not exist by themselves any more than pleasures and pains, memories and flashes of insight. All these are brain processes. However, nothing prevents us from *feigning* that there are ideas, that they are "there" up for grabs – which is what we do when saying that someone "discovered" such and such an idea. We pretend that there are infinitely many integers even though we can think of only finitely many of them – and this because we assign the set of all integers definite properties, such as that of being included in the set of rational numbers. Likewise we make believe that every deductive system contains infinitely many theorems – and this because, if pressed, we can prove any of them. All such fictions are mental creations and, far from being idle or merely entertaining, are an essential part of modern culture. But it would be sheer animism to endow such fictions with real autonomous existence and causal efficacy – the way idealist philosophers from Plato on have been doing, or the way Popper (1968, 1972, 1974, 1977) does. A differential equation does not exist by itself and therefore is harmless; only thinking of it can have some effects. In short, ideas in themselves are fictions and as such have no physical existence.

5. SELF TO SOCIETY

5.1. *Awareness, Consciousness, Will*

While many mentalists equate consciousness with mind, and behaviorists have no use for either concept, physiological psychologists, neurologists and even ethologists are feeling the need for both. For example, the mere description of yoga experiences, such as the voluntary control of heartbeats, uses the concept of initial conscious control. Unfortunately the concept of consciousness is still rather vague – particularly among those who advocate its use but refuse squarely to define it (e.g. Popper and Eccles, 1977).

We start by distinguishing consciousness from awareness. We say that an animal is (or fails to be) *aware* of what goes on in its environment or in itself (in particular, of what it does or is done to it). Only if the animal is aware of some of its own brain processes (not necessarily mental ones) shall we say that it is *conscious*. More precisely, we make

DEFINITION 4.42 If b is an animal,

(i) b is *aware* of (or *notices*) stimulus x (internal or external) iff b feels or perceives x – otherwise b is *unaware* of x;

(ii) b is *conscious* of brain process x in b iff b thinks of x – otherwise b is unconscious of x.

Whereas awareness requires only a sensory system, consciousness requires also intelligence, i.e. the ability to think, and moreover to think of brain events. The lower animals can be aware but not conscious, and a conscious subject may be unaware of some external stimuli. So, we make

POSTULATE 4.20 All animals are aware of some stimuli and some are also conscious of some of their own brain processes.

DEFINITION 4.43 The *consciousness* of an animal *b* is the set of all the states of the CNS of *b* in which *b* is conscious of some CNS process or other in *b*.

In other words, consciousness of brain event *x* is direct knowledge of *x*. (This is what introspection is all about.) Moreover we may hypothesize that a conscious event is a brain activity consisting in monitoring (recording, analyzing, controlling, or keeping track of) some other brain activity, much as a voltmeter measures the electromotive force between two points of an electrical network. I.e. we adopt

POSTULATE 4.21 Let *P* be a subsystem of the CNS of an animal *b* engaged in a mental process *p*. Then the CNS of *b* contains a neural system *Q*, other than *P* and connected with *P*, whose activity *q* equals *b*'s being conscious (thinking) of *p*.

This hypothesis is far from outlandish: after all, every biosystem is a control biosystem, i.e. it monitors (watches and checks) its own activity. By sensing and correcting its own functioning, the biosystem assures normality or return to it. So, it should come as no surprise that the brain, the most complex of biosystems and the supreme control of the animal, is capable of controlling its own activity.

Since by hypothesis two distinct and interconnected neural systems are involved in all conscious states, it is perfectly possible for them to interact. Thus if a subject is conscious of a routine mental task, he or she may bungle it: the monitoring interferes with the execution of the well learned task. If on the other hand the subject is beginning to learn a task, he had better be both aware and conscious of it: the monitoring system will guide the establishing of the psychon. To account for such phenomena there is no need to invoke an immaterial consciousness (as Sperry, 1969, Popper and Eccles, 1977, and so many others have done). If one wishes to speculate on the causal efficacy of conscious events, then he ought to do it within the scientific framework of changing things instead of the mythical framework of disembodies entities.

Since awareness and consciousness are activities of a biosystem, they can be dimmed or heightened by appropriately inhibiting or stimulating the neural components involved. Such degrees are nothing but the intensities of the activities of the corresponding neural control systems. If consciousness were a separate entity we would not know how to explain such variations and, in particular, the daily obliteration and resurgence of consciousness.

It is a well known law that, as learned tasks are repeated, they tend to become automated, i.e. unconscious:

POSTULATE 4.22 In the course of the life of an animal capable of learning, learned behavior, if initially conscious, becomes gradually unconscious.

When automatisms prove insufficient to solve a problem or execute a task, it proves convenient to become conscious or to heighten the level of conscious mental activity. A conscious animal is better equipped to cope with novelty, for it can evaluate its own thoughts and actions, criticizing and correcting them if necessary. (For the adaptive advantages of consciousness see Griffin, 1976.) Given the biovalue of consciousness as a device for instant adaptation, it is no wonder that man has been so successful, for his CNS is the only one capable of generating conscious states almost at will.

Consciousness, then, is not an entity but a set of states of a highly evolved CNS. Therefore to speak of 'states of consciousness' is sheer reification: there are only conscious (and unconscious) states of the brain. (Recall Fig. 4.3 in Sec. 2.2.) Likewise it is mistaken to speak of the Unconscious (or the Subconscious) as an entity, in particular one capable of influencing Consciousness (another entity). There are only brain events, some conscious and the others unconscious, and because they are concrete events they can influence others. What holds for consciousness and unconsciousness holds also for Freud's Id and Superego. There can be no mental entities within mental entities, because mental entities are nonentities. Surely there are controls, e.g. feedback systems, in the brain. Some such controls may "censor" (inhibit) certain brain activities, e.g. block the flow of information to the system doing the monitoring, or the activity of the psychon(s) doing the thinking. For example one may have learned an item A and, in the course of mental work, think an item B incompatible with A. If A is deeply ingrained, it may "repress" or "suppress" B, i.e. inhibit the psychon that does B. But if B is as vivid as A, further psychons may be activated until the "contradiction is resolved" in favor of one of the original options or of a third one. Physiologically, this is nothing but an interplay among competing neural feedback circuits.

Our next topic is volition, or conscious purposeful behavior:

DEFINITION 4.44 An animal act is *voluntary* (or *intentional*) iff it is a conscious purposeful act – otherwise it is *involuntary*.

The will is not an entity but a neural activity: x wills y iff x forms consciously the purpose of doing *y*. Nor is the will a mysterious faculty of an immaterial mind, but a capacity of highly evolved CNSs, namely "a control of behavior by the thought process" (Hebb, 1968, p. 75). When you pick a fruit from a tree or a book from a shelf, and are aware of what you are doing and moreover have a definite purpose in doing so, what happens is that certain psychons in your associative cortex – most likely psychons located in the frontal lobes – activate certain motor centers (in particular the gyrus), which in turn control the movements of the limbs. Thus *intentions can cause behavior*. Curiously enough this is also a thesis of the dualist philosophers who defend the "intentionalist" (as opposed to the scientific) explanation of human behavior. However, they have no right to do so because causal relations obtain only between events, and the dualists refuse to regard intentions as (neural) events.

Voluntary acts can be free or compelled. The general who decides to launch an attack may act freely, but those of his soldiers who go unwillingly to battle act voluntarily though under compulsion. Free will is volition with free choice of goal, with or without foresight of possible outcome. We make then

DEFINITION 4.45 An animal acts of its own *free will* iff

(i) its action is voluntary and

(ii) it has free choice of its goal(s) – i.e. is under no programmed or external compulsion to attain the chosen goal.

Free will has of course been either affirmed or denied for theological or philosophical reasons. In our theory it follows from Postulate 4.20 and Definitions 4.44 and 4.45:

THEOREM 4.3 All animals capable of being in conscious states are able to perform free voluntary acts.

If consciousness is not exclusively human, neither is free will. And both are legitimate subjects of scientific research.

5.2. *Person and Self*

There are a number of concepts of a person. We are interested in this one:

DEFINITION 4.46 If *b* is an animal endowed with a plastic neural system capable of mentation (i.e. with a nonvoid mind), then

(i) the *personality* of b is the functional system composed of all the motor and mental functions of b;

(ii) a *person* is an animal endowed with a personality.

Remark 1 It follows that not only humans but all animals with mental abilities are entitled to be called 'persons'. *Remark 2* Personality is a whole-body property: there is no special organ of personality, since it is defined as the union of behavior and mentation. *Remark 3* For the same reason the destruction or ablation of considerable portions of the CNS, as well as the amputation or the paralysis of limbs, ensue in personality changes. Irreversible and massive destruction of the brain destroys personality altogether, in which case the animal ceases to be a person both psychologically and legally. *Remark 4* Learning shapes and often enriches personality; it can even produce radical personality changes. *Remark 5* People who undergo shattering experiences (war, concentration camp, prison, or ideological conversion) may acquire whole new personalities. *Remark 6* In deep sleep or in coma we lose much if not all of our personality: we become nonpersons or nearly so. (But of course when reawakening we recover – or rather reconstruct – our personality.) *Remark 7* Since the behavior and the mentation of animals endowed with plastic neural systems depend partly on their environment, one and the same animal is bound to exhibit different personalities in different environments – e.g. a tyrant at home and meek at work. (For the various determinants of personality see Gray, (1972b).) *Remark 8* There is no personal identity or enduring personality any more than there is digestive or cardiovascular identity: the behavior and the mentation of a higher vertebrate are more changeable and vulnerable than any other bodily function. (For an early criticism of the idea of personal identity see Hume, 1739, Part IV, Sec. VI.) *Remark 9* Since mind is not incorporeal stuff but a collection of brain functions, and since there are no two strictly identical brains, "identical" twins reared in the same family have different minds, hence are different persons instead of constituting (as Shaffer, 1977, has claimed) a single mind with two bodies. *Remark 10* Since split brain patients have two minds (Corollary 4.7), they also have a double personality, i.e. they are two different persons united anatomically. *Remark 11* If an individual were to get a new brain by transplant, the personalities of both donor and recipient would disappear, and a third personality would emerge. Indeed, the brain in its new encasement would receive new stimuli and fail to receive some of the customary stimuli. And, because it would be controlling a different body, it would effect different movements, so it would function differently. The original selves would be lost. The same holds, *a fortiori*, for the transplant of each hemisphere into a different skull: two different persons would be manufactured – possibly neither of them viable. In short, tampering with a minding body involves tampering with its mind.

Finally we come to the notion of self, which in our theory is elucidated by

DEFINITION 4.47 An animal

(i) has (or is in a state of) *self-awareness* iff it is aware of itself (i.e. of events occurring in itself) as different from all other entities;

(ii) has (or is in a state of) *self-consciousness* iff it is conscious of some of its own past conscious states;

(iii) has a *self* at a given time iff it is self-aware or self-conscious at that time.

Remark 1 This concept is more restrictive than that of mind: all animals possessing a self (i.e. all selves) mentate but the converse is false. *Remark 2* The self is not an entity but a state of an entity, namely an advanced brain. Therefore in the context of our theory to say that the self has or uses its brain (Toulmin, 1972; Popper and Eccles, 1977) amounts to saying that certain brain states have a brain. *Remark 3* Possibly animals other than humans have self-awareness but, so far as we know, only humans have *self*-consciousness, at least when normal and past their infancy. The young child is self-aware but not self-conscious. Self-consciousness is generally believed to appear at about seven years of age (Piaget) and is sometimes conjectured to originate as internalized speech, hence as a spinoff of social life (Vygotskii, 1962; Luria, 1969). It is therefore as old as language, and both have evolved (and continue to evolve) together with society. But the subject of sociality deserves a new subsection

5.3. *Social Behavior*

A bird's territorial call and a criminal's "antisocial" action are no less social than a bee's dance or a baboon's scouting on behalf of its troop, even though the former actions tend to reinforce solitude while the latter strengthen gregariousness. (Cf. Hinde, 1974.) The notion in question is elucidated by

DEFINITION 4.48 An animal engages in *social behavior* iff it acts on, or is acted upon by, other individuals of the same genus.

The condition of congenericity excludes preying and flight from predators from the social behavior repertoire but on the other hand includes reproductive behavior. Needless to say, social behavior may be automatic, in particular genetically programmed, as is the case with insects.

Although not all animals are gregarious or social (i.e. live in communities), all are social in the above sense, if not actually at least potentially. We assume therefore

POSTULATE 4.23 The behavioral repertoire of every animal includes types (patterns) of social behavior.

Like all behavior, social behavior is controlled both internally – in particular by the NES – and externally. For example, aggressiveness depends upon endogenous variables such as certain hormones (in particular testosterones) and the excitation of certain brain systems (e.g. the anterior hypothalamus), as well as upon exogenous variables, such as scarcity of food, cold, and crowding. Consequently biological determinism, which holds that all social behavior is determined exclusively by endogenous variables, holds only for animals whose social behavior repertoire is inherited, hence stereotyped. The social behavior of bees and ants, the ritualized courtship of birds, and the patterns of aggression and submission of cichlid fish and even of wild dogs, seem to be of that kind. On the other hand primates seem to inherit only those patterns of social behavior that concern reproduction and the care of the young: all others are learned. What primates do inherit is (*a*) the *need* for social intercourse and (*b*) the *capacity* to form and change rules of social behavior, and to form and undo social groups.

Animals get together to form families or communities, temporary or permanent, loosely or tightly knit, when such behavior improves their lot. The simplest such system is the family, and the simplest family is the mother–infant couple. The root of such a system is of course the care of the young. Note that families, though formed naturally – i.e. on the strength of natural bonds – are not biosystems. Only the components of a family are alive, i.e. metabolize, are capable of reproducing, etc. A family is a social system. We shall make a detailed study of social systems in the next chapter, but will offer now a definition that will be useful for our sociobiological considerations:

DEFINITION 4.49 A system σ is a *sociosystem* (or *social system*, or *social group*) iff

(i) the *composition* of σ is a set of animals of the same order (not necessarily the same species);

(ii) the *environment* of σ is the set of things, other than the components of σ, that act on or are acted on by the latter;

(iii) the *structure* of σ is the social behavior repertoire of the members of σ.

Every society is a sociosystem but the converse is not true: industrial plants, schools, and clubs are sociosystems but not societies. A society is a self-reliant sociosystem:

DEFINTION 4.50 A sociosystem is a *society* iff it is self-sufficient [i.e. does not depend entirely upon other sociosystems].

This definition will be refined in the next chapter.

5.4. *The Root of Social Cohesion*

What elicits the formation of a social system and keeps it together despite the somewhat divergent interests of its members? Our answer is this: rearing of the young in the case of the family, sharing (or participating) in the case of other sociosystems, and social pressure (peaceful or forceful) in all.

Cooperation need not be conscious: it can be automatic, as among social insects. Animals can cooperate either in their own individual interest (as is the case with sexual partners and with partners in a foraging expedition) or in the interest of their group – as in the case of an ant colony or a wolf pack. The general concept is elucidated by

DEFINITION 4.51 If a and b are animals, then a and b *cooperate* with one another iff the social behavior of each is valuable to the other or to a third animal.

When cooperation concerns things (e.g. goods) of some kind, it is called *sharing*, and *participation* when it concerns activities. More explicitly:

DEFINITION 4.52 Let σ be a social system with composition $\mathscr{C}(\sigma)$, environment $\mathscr{E}(\sigma)$, and structure $\mathscr{S}(\sigma)$. Further, let $T \subset \mathscr{C}(\sigma) \cup \mathscr{E}(\sigma)$ be a set of members of σ or of items in the environment of σ, and $A \subset \mathscr{S}(\sigma)$ a kind of activity in σ. Then for any component x of σ,

(i) x *shares* in T iff x cooperates with other member(s) of σ in acting on items in T;

(ii) x *participates* in A iff x cooperates with other member(s) of σ in doing A.

Now our hypothesis that association is based on cooperation:

POSTULATE 4.24 A set of conspecific animals forms a social system if and only if each of them cooperates with some other members of the same set [i.e. shares in the resources of the society or participates in some of its activities].

The early evolutionists stressed competition at the expense of cooperation, and both Freud and Lorenz regarded aggression as instinctive and pervasive. We have learned since that the struggle for life involves both. For example, flocking and the formation of colonies are effective defenses against predation (Hamilton, 1971). Group grazing, hunting in packs, and active defense involve cooperation – not to speak of higher forms of sociality such as division of labor and games. No cooperation, no sociosystems.

Only some forms of cooperation are purposeful, even fewer conscious. Purposeful cooperation deserves a name of its own:

DEFINITION 4.52 For any animals a and b,

(i) a behaves *altruistically* (or with *solidarity*) towards b iff a engages in purposeful social behavior that may be of value to b though not directly or immediately to a;

(ii) a and b are *reciprocally altruistic* (or *solidary*) iff a is altruistic towards b and conversely.

A rough measure of solidarity is this. Let a and b be animals, and $N(b)$ the set of needs of b (e.g. food, shelter, or care), and $G(a, b)$ the set of items a is prepared to give b. (Both $N(b)$ and $G(a, b)$ are taken during the same period of time.) Then the solidarity of a towards b is $G(a, b) \cap N(b)$. A quantitation of this concept is the following. *The degree of solidarity* of a towards b (over the same period) is

$$s(a, b) = |G(a, b) \cap N(b)| / |N(b)|.$$

(The more you give needed items the more solidary your behavior. Items that are not needed do not count.) The reciprocal solidarity between a and b is of course $s(a, b) + s(b, a)$. This measures the total number of items exchanged between a and b without regard to their value.

A more precise concept is easily constructed by assigning a value to each item needed and got. Such value need not be biological or psychological: in the case of higher animals it can be social, i.e. the items being traded off may benefit the social group as a whole. If only for this reason one can hardly subscribe to the cost-benefit analysis of altruism championed by Hamilton (1964) and Wilson (1975). This rests on the assumption that genes are so smart and species-conscious that they know it is good business for an individual to lay down its life for three or more sibilings, for in this case the chances are that its full genetic equipment (or rather a replica of it) will be saved for the benefit of posterity. Altruism requires a highly developed CNS capable of becoming aware that a conspecific is in need. Skipping levels, the way some sociobiologists do, won't do. (See Ruse (1979) for a balanced assessment of sociobiology.)

In addition to the inter individual actions that keep sociosystems going, there are the group influences on the individual that prevent it from rending the social fabric. Social pressure is not a mysterious action of the whole on the part but rather the action (direct or indirect) of the various components of a social group on those that deviate from the norm or mode. One way of elucidating the concept is by means of

DEFINITION 4.54 Let F be a function representing a property of members of a social system σ, and assume that the distribution of F in $\mathscr{C}(\sigma)$ is bell-shaped with average $\bar{F}$ and scatter d. Then, for any member x of σ,

(i) x *conforms* with respect to F iff $|F(x) - \bar{F}| < d$;

(ii) x *deviates* with respect to F iff x does not conform with respect to F.

We shall assume the obvious, namely that every social group contains some deviants, and that the group pressure on an individual increases with its deviance:

POSTULATE 4.25 In every social system (a) there are deviants in some respects, and (b) some of the fellow members of the deviant components subject them to a pressure that is a monotonically increasing function of the deviance.

In most vertebrate societies social structure has a rather weak reaction on individual behavior. Indeed flocks and troops of various kinds split and even dissolve altogether under altered environmental conditions. In hierarchical primate societies, on the other hand, the over-all social structure seems to be overpowering as long as the social system lasts. This makes for social stability – as well as for the occasional rebellion. The deviant, underprivileged, or just young, are often outcast. In a few cases they may find a more favorable habitat offering new opportunities and new challenges. In other cases the deviants may join forces to attempt a restructuring of their group. In any case, just as genic variety is a motor of biological evolution, so social deviance is a motor of social evolution.

5.5. *Communication*

All social animals, and many which are not, can exchange information of some kind, and some of them using a great variety of means. We shall adopt some of the standard concepts used in describing animal communication (Morris, 1938; Smith, 1965). They are all included in

DEFINITION 4.55 (i) An *animal signal* is a physical process executed or controlled by an animal, perceptible to other animals and capable of altering their behavior;

(ii) the *message* carried by an animal signal is an encoded representation of events in the CNS of the signalling individual;

(iii) the *significance* of a message to a recipient is the change in the latter's CNS caused by the signal carrying the message;

(iv) an animal *understands* a message if the events triggered in its CNS by the carrier signal are similar to those in the animal that emitted the signal;

(v) two animals *communicate* iff they understand the messages of the signals they exchange.

Remark 1 An animal signal may be blunt, as in pushing, or subtle, as in singing. *Remark 2* Communication is always among animals, though it is not always direct. For example, we do not communicate with computers but through them. *Remark 3* Although communication can be valuable (or disvaluable), it is not necessarily purposeful. For example, the signals exchanged by social insects, being genetically programmed, are not purposeful even though they are functional (biovaluable). *Remark 4* The psychoneural concept of significance (Definition 4.55 (iii)) differs from both the behavioral notion (Morris, 1938; Paivio, 1971) and the semantical one (Vol. 2, Ch. 7).

Not every set of signals is a language. For example, the set of human gestures is not a language. A language is a system of learned signals and moreover one that allows an animal to compose an unlimited number of distinct messages. A single signal suffices to build a language if allowed to concatenate with itself; on the other hand bees communicate without having a language: they do not learn their signals from scratch and they cannot generate an unlimited number of signals out of a few simple ones. The following convention summarizes all this:

DEFINITION 4.56 Let S be a finite nonempty set, and $\circ$ a binary operation in S. Further, call $\mathscr{L} = \langle S^*, \circ \rangle$ the free semigroup on S [i.e. the set of concatenates of members of S]. Then $\mathscr{L}$ is a *language* iff

(i) S^* is a set of learned animal signals;

(ii) there is at least one animal capable of understanding some of the messages carried by members of S^*.

Remark 1 This definition allows for private languages such as those deaf children can invent (Goldin-Meadow *et al.*, 1977). Incidentally, Wittgenstein and his followers have denied that private languages could exist. *Remark 2* Chimpanzees can learn certain sign languages (Gardner and Gardner, 1969). This finding has weakened the hypothesis that language is exclusively human – weakened rather than refuted, for the chimpanzees in question were taught a man-made language, namely the American Sign Language or ASL, whereas humans *create* languages. Moreover, although ASL has as much expressive power as any natural language, chimpanzees cannot make full use of it because they cannot think all human thoughts. *Remark 3* By using borrowed languages, chimpanzees can express thoughts of their own and thus refute the dualist's contention that it is "really senseless to conjecture that animals *may* have thoughts" (Malcolm, 1973). We are now sure, on the basis of experiments with teaching artificial languages to chimpanzees, that animals can think. *Remark 4* Because chimpanzees can be trained to communicate not only by means of ASL but also with the help of plastic chips (Premack, 1971) and via computers (Rumbaugh *et al.*, 1973), man can no longer be defined as *the talking animal*. On the other hand we can evidently postulate that humans (and chimpanzees and possibly other animals as well) have an innate linguistic ability or potentiality or disposition. This is not to say that man is born with a knowledge of certain basic structural features common to all natural languages. What we are born with is the vocal tract, the Wernicke and Broca areas, and subsidiary neural systems – as well as a social environment, carrier of a tradition, that stimulates the acquisition and development of verbal languages.

5.6. *Protoeconomy, Protoculture, Protopolity*

In the next chapter we shall argue that every human society, no matter how primitive or evolved, is composed of four main subsystems: kinship, economy, culture, and polity. We submit that all four are already found *in nuce* in some prehuman societies.

That prehuman societies have a kinship system, i.e. a social network based on reproduction, seems obvious. Nor is there any doubt that some have also an economic system, i.e. a social network based on work. As for politics in the large sense of management of social activities, it is well known than in certain animal societies law and order, as well as defense, are well organized. (Cf. Gray Eaton (1976) for the case of the Japanese macaque society.) Less well known, but true nonetheless is that some prehuman societies have a culture of sorts, i.e. a system whose members engage in social activities that are mental rather than biological, productive, or managerial. The patterns of such activities can moreover be transmitted throughout the community as well as handed over to the next generation – i.e. traditions are formed, spread, and are kept. Such a transmission is effected by imitation and occasionally also by teaching, hence with the help of signals. This has been found to be the case among Japanese macaques (Kawai, 1965) and chimpanzees (Menzel *et al.*, 1972). In both cases the initiation of new traditions called for some bold individuals – creative deviants – that sought newness rather than fearing it.

Because economic, cultural and political systems are already found in prehuman societies, although in a primitive form, we should characterize the corresponding concepts:

DEFINITION 4.57 If σ is an animal society, then

(i) the *economy* of σ is the subsystem of σ whose members engage in the active and organized transformation of the environment of σ;

(ii) the *culture* of σ is the subsystem of σ whose members engage in mental activities that control (or are controlled by) some of the activities of other members of σ;

(iii) the *polity* (or *political system*) of σ is the subsystem of σ whose members control (or are controlled by) the social behavior of other members of σ.

A particular case is that of tripartite societies composed of absolutely creative animals, i.e. animals capable of discovering and inventing certain things before any other animals (Definition 4.41). We submit that this is the case of all humans, from *Homo erectus* through *habilis* and *sapiens* to *sapiens sapiens*, i.e. us. That is, we assume

POSTULATE 4.26 An animal society is *human* iff

(i) some of its members are absolutely creative, and

(ii) it is composed of an economy, a culture, and a polity.

Remark 1 We are defining humanness in psychological and sociological rather than purely biological terms. In this we follow the tradition of anthropology and prehistory, and reject Neo-Darwinism. *Remark 2* Clause (i) suggests that the economy, the culture and the polity, far from being rigid, are plastic – as plastic as their members. Man is not only an economic, cultural and political animal, but also one that can alter very quickly almost any feature of this triad without having to wait for genic mutations or environmental cataclysms: man is the supreme creator and destroyer.

We now have all the preliminary material necessary to build an ontology of human society – a task for the next chapter.

6. CONCLUDING REMARKS

Wind is the motion of air: there is no wind apart from moving air. Likewise there is no metabolism over and above metabolizing systems, or social change over and above social systems. In every factual science, states are states of concrete entities, and events are changes of state of such objects. It is only in traditional psychology and philosophy of mind that talk of behavior independent of behaving animals, and of mentation alongside or above the brain, is tolerated, nay encouraged by the dualist myth. This separation between the mind and that which does the minding – between function and organ – has kept psychology and the philosophy of mind far apart from neurobiology and has prevented a full utilization of the scientific approach to the mind-body problem. The philosophy of psychophysical dualism is responsible for the backward state of research into that problem. Anyone interested in the progress of the science of mind must therefore reject the prehistoric myth of the autonomous mind.

The rejection of psychophysical dualism does not force one to adopt eliminative materialism in either of its versions – i.e. that mind and brain are identical, that there is no mind, or that all things have mental capacities. (This last version is of course indistinguishable from panpsychism or animism.) Psychobiology suggests not just psychoneural monism – the strict identity of mental events with brain events – but also emergentism, i.e. the thesis that mentality is an emergent property possessed only by animals endowed with a very complex plastic nervous system. This ability confers its owners such decisive advantages, and is related to so many other properties and laws (physiological, psychological, and social), that one is justified in asserting that the organisms endowed with it constitute a level of their own – that of *psychosystems*. However, this is not saying that *minds* constitute a level of their own, and this simply because there are no disembodied (or even embodied) minds, but only *minding bodies*. (The dual notions of embodiment and disembodiment are rather vague and typically dualistic, hence – *pace* Margolis (1978) – have no place in a science-oriented ontology.)

To repeat the same idea in different words: One can hold that the mental is emergent relative to the merely physical without reifying the former. That is, one can hold that the mind is not an entity composed of lower level things – let alone a thing composed of no entities whatever – but a collection of functions (activities, processes) of certain neural systems, that individual neurons do not possess. And so emergentist (or systemist) materialism, unlike eliminative materialism, is seen to be compatible with overall pluralism, or the ontology that proclaims the qualitative variety and mutability of reality. (Cf. Vol. 3, Ch. 5.)

Our espousing emergentist (or systemist) materialism does not entail claiming that it has already solved the mind-body problem. It has and it won't, for emergentist materialism is a philosophy providing only a scaffolding or general framework for the detailed scientific investigation of the many problems one lumps under the rubric 'the mind-body problem'. It behoves neuroscientists and psychologists to attack these problems – as scientists not as amateur philosophers let alone theologians. (Likewise emergentist materialism provides only a general framework for the detailed investigation of the problems of inanimate matter and of life, both of which are just as bottomless as the problem of mind.)

However, philosophy is far from behaving as a nonparticipant spectator of the scientific investigation of the mind-body problem. The dualist philosophy of mind has for centuries actively blocked the scientific approach to the problem. On the other hand emergentist (or systemist) materialism contributes to the scientific investigation of it by (*a*) dispelling confusions, (*b*) exposing myths, (*c*) suggesting that all problems about mental states or processes be construed as problems concerning brain functions, and therefore (*d*) encouraging the building of neural models of mental functions. As a matter of fact emergentist (systemist) materialism is the philosophy of mind behind physiological psychology, psychochemistry, and neurology. It is the only one that has been fruitful, that does not support quixotic reductionism, and that is compatible with a systemist and dynamicist ontology as well as with all the sciences.

CHAPTER 5

SOCIETY

This chapter is devoted to human society. Whereas to biologism human society is just one more animal society, according to spiritualism it is nothing of the sort because it is guided by ideas and values. We take the alternative view that human society is an animal society with many and remarkable novel properties, only a few of which it shares with animal protoeconomies, protocultures, and protopolities. We assume that man is neither an animal at the mercy of its genetic makeup and its environment, nor a free spiritual being akin to divinity: man is, instead, the primate that works and strives to know, that builds, maintains, and transforms social organizations far beyond the call of the gene or the environment, and that creates artistic, technological, and intellectual cultures, and also plays. Man is *faber* and *sapiens, oeconomicus* and *politicus, artifex* and *ludens*.

No aspect of mankind can be properly understood unless one keeps in mind the fivefold character of human nature – biological, psychological, economic, cultural, and political. The very existence of human society – of its economy, culture, and polity – has biological roots that cannot be cut, and psychological constraints that cannot easily be bent. There is no philosophizing on an empty stomach and, from a certain point on, no subsistence without new thinking, cooperating, and organizing. The biological, psychological, economic, cultural and political aspects hang together.

Human society is composed of animals but is not rigidly determined by biological factors, as shown by the variety of types of society. Moreover social behavior reacts on the animal basis by selecting socially or culturally valuable traits. This process may even oppose that of natural selection, as when the handicapped are protected. Thus social selection modifies genetic composition. For example whereas urbanization and crowding select resistance to stress and foul air, and perhaps also pushiness and resistance to bureaucacy, it abates other features. Such a social selection of biological and psychological traits modifies the genetic composition of the population, a change that has in turn social consequences. In sum there is a tight relationship between the biological and the social.

Consequently mankind does not evolve exactly as other species do: the theory of evolution does not apply to it nowadays the way it did a couple of million years ago. In fact we should distinguish three modes of evolution: "blind", animal, and social. "Blind" evolution is evolution by mutation, recombination and natural selection; it is the way molecules and plants evolve. Animal evolution combines genic change with behavior: the environment selects not only phenotypes but also behavior patterns, and animals adapt not only phylogenetically but also ontogenetically by learning adaptive behavior. Finally social evolution proceeds not only by genic change and behavioral change, but also by social creation and selection.

In all three cases the individual proposes and its environment decides – metaphorically speaking. But in the cases of animal and social evolution the individual learns and the environment, rather than being given to it, is partly chosen by and and partly even remade by it. And in the case of social evolution there are not only biological and psychological factors but also economic, cultural, and political ones. Moreover, thanks to language and social life, some of the learned skills and some of the products of human activity are transmitted to the new generations: here we can speak of the (social) inheritance of acquired characters. But even this inheritance is plastic, for we are free either to disregard or to enrich our heritage.

In the present chapter we shall examine the social aspect of man, centering our attention on social relations and the resulting social structure. Our aim will be to clarify and interrelate some of the key concepts of the social sciences – those which are so basic that no particular social science deigns to clarify them. We shall do it from a point of view that supersedes not only biologism and spiritualism, but also individualism and holism. This alternative is of course the systemist one. By regarding human society as a concrete system of a particular kind, and by analyzing the various subsystems and supersystems of society, we hope to attain some clarity about a traditionally obscure subject. Needless to say, our discourse will be extremely general: it will aim at some of the so-called cultural universals. Therefore we shall not be able to explain or predict any specific social events. We shall at the most supply a scaffolding for building specific theories in the social sciences.

1. HUMAN SOCIETY

1.1. *Definitions*

Our Postulate 4.26 characterizes a human society as an animal society containing some absolutely creative members, and composed of an economy, a culture, and a polity. That postulate served the purpose of defining (implicitly) humanness rather than human society. We shall now define the latter in some detail, assuming that biology, psychology and psysical anthropology can take care of the biological characteristics of *Homo*.

We submit that the chief characteristic of human society, in contradistinction to other animal societies, is that it possesses jointly all the following properties:

(i) some members of every human society do *labor*, i.e. engage habitually in the deliberate transformation of part of their environment (*homo faber*);

(ii) the workers use *tools* made in standardized patterns and work with them according to rules or *techniques* that they have invented, improved, or learned;

(iii) some members of every human society *manage* (direct or control or contribute to either directing or controlling) the activities of others: they organize labor or games, learning or fighting;

(iv) some members of every human community engage habitually (though perhaps not exclusively) in *cultural activities* – cave painting, story telling, tool designing, healing, reckoning, teaching skills, advancing knowledge, etc. (*homo culturifex*);

(v) all members of every human society devote some time to playing – sex, dancing, play-acting, racing, playing hide and seek, games of chance, etc. (*homo ludens*);

(vi) all members of every human society *communicate* with some other members of the same society or of other societies by means of standardized signs, in particular a language;

(vii) every member of every human community *shares* information, services or goods with some other members of the same community;

(viii) all the members of every human society *learn* attitudes, skills and information not only from their parents but also from other members of their community (by imitation or formal teaching);

(ix) every human society is divided into *social groups*, such as families and occupational groups;

(x) every human society lasts as long as every member of it *participates* to some extent in several social activities and benefits from such participation.

Surely other animals too work – e.g. bees and beavers. But they make no tools. Still others use natural tools, such as branches, stones or thorns, but only occasionally and in any case not fashioned by them or at least not to standardized patterns. Again, some birds and mammals play, and still others have evolved coded sign systems (though not languages proper). However, only humans organize (manage) some of their own activities, *and* teach behavior patterns and feeling and thinking patterns, *and* create novel objects (artifacts, works of art, organizations, words, etc.). In sum only humans possess, socially if not individually, *all ten* properties listed above.

The preceding characterization of human society, though sketchy, suffices for the moment. We proceed to express it in terms of concepts elucidated in the previous chapters:

DEFINITION 5.1 A concrete system σ is a *human society* (or *community*) iff σ is an animal society such that

(i) the *composition* $\mathscr{C}(\sigma)$ of σ is included in the set of human beings (i.e. the genus *Homo*, not necessarily our own species);

(ii) the *environment* $\mathscr{E}(\sigma)$ of σ contains some of the items necessary for the survival of some of the components of σ;

(iii) the *structure* $\mathscr{S}(\sigma)$ of σ equals the disjoint union of two sets of relations, S and T – called *social relations* and *transformation relations* respectively – such that

(a) S includes the relation of biological descent and all other (kinship) relations derived from it;

(b) every member of the set S of social relations is accompanied by communication (information flow);

(c) S includes the relations of sharing (goods and services) and participating (in social activities);

(d) S includes a nonvoid set $M \subset S$, called *management*, such that every member of M is a relation in some Cartesian power of the membership $\mathscr{C}(\sigma)$, and representing some habitual actions of members of σ upon fellow members, consisting in controlling certain relations in S (e.g. courtship and learning) or in T (e.g. hunting and ploughing);

(e) the set T of transformation relations includes a nonempty set $W \subset T$, called *work*, such that every element of W is a relation from a subset of $(\mathscr{C}(\sigma))^p \times (\mathscr{E}(\sigma))^q$, with $p, q \geq 1$, into a nonvoid proper subset A of $\mathscr{E}(\sigma)$, representing the habitual transformation, by some members of σ, of certain things in $\mathscr{E}(\sigma)$ (e.g. iron ore) into things in A (e.g. iron tools) called *artifacts*;

(iv) the social relations S and the transformation relations T generate equivalence relations inducing partitions of the membership of σ into social groups (social differentiation);

(v) σ is self-supporting as long as it lasts, i.e. is capable of satisfying its needs by work.

According to this definition not every bunch of humans, not even every sociosystem (Definition 4.49), constitutes a human society: to qualify as such a collection of humans must share an environment, transform the latter deliberately (by work, not just by wearing it out), hold social relations and communicate among themselves, be divided into social groups, and constitute a self-reliant unit. Thus a factory, a school and an army, though subsystems of a society and therefore sociosystems, are not societies. Further, the social relations among the members of the society must include man-transforming relations M such as educating, organizing and coercing, and they must be set up and maintained with the help of communication.

So much for a quick characterization of the concrete systems we call 'human societies', that make up the membership of the set of all human societies – past, present, and future. Let us emphasize that they are systems, not just either things or aggregates of such – let alone supraindividual entities of an immaterial nature. Note also that, although societies are composed of organisms, they have no organismic properties: they do not synthesize proteins, reproduce by cell division or conjugation, etc. In fact societies have bulk or systemic properties, some of which are peculiar to them:

DEFINITION 5.2 Let P be a property. Then

(i) P is a *societal property* iff there exists (now or at any other time) a human society possessing P;

(ii) if P is a societal property of some society σ, then P is a *resultant* property of σ iff P is also a property of some components of σ;

(iii) if P is a societal property of some society σ, then P is an *emergent* property of σ iff P is not a resultant property.

Example 1 The total food consumption per year of a given society is a resultant property of it for being the mere additive aggregation of the individual consumptions. Not so the total energy consumption, let alone the total production, for they are social. Likewise the family structure, the political organization, and the cohesiveness of a community are emergent societal properties. *Example 2* All members of a society possess properties that are neither individual nor societal, such as shyness and conformity (or its dual, deviance). Take the latter, analyzed by Definition 4.54. In it 'F' represents a property of an individual, the average $\bar{F}$ a resultant property of a sociosystem, and the standard deviation d of the distribution of F values in the society represents an emergent property of the latter. (So much so that if d is small we can say that the sociosystem is conformist.)

Our first hypothesis is that the concept of an emergent societal property is not idle:

POSTULATE 5.1 Every society has emergent properties.

We hasten to note, though, that 'emergent' does not mean "unexplainable" or "unpredictable". Firstly, because "emergence" is an ontological not an epistemological category. Secondly because it is the business of science not only to acknowledge emergence but also to incorporate it into theories and thus render it understandable and sometimes also predictable.

1.2. *Subsystem, Supersystem, Specific Function*

Every society, no matter how primitive, is composed of various subsystems. And almost every contemporary human society is a subsystem of a more inclusive social system, such as a province, a nation, a regional system, or the world system. So, we need

DEFINITION 5.3 Let σ be a human society. Then

(i) any social system σ' such that σ' is a subsystem of σ (i.e. $\sigma' \precsim \sigma$) is a *social subsystem* of σ;

(ii) any society σ' such that σ is a subsystem of σ' (i.e. $\sigma \precsim \sigma'$) is a *social supersystem* of σ.

Example The health system of a modern community is a subsystem of it characterized by the following coordinates:

Composition: physicians, nurses, administrators, clerks, janitors, inpatients, out-patients, etc.;

Immediate environment: hospital buildings, furniture, instruments, ambulances, families of the members of the system, etc.;

Structure: relations of diagnosing and prognosticating, medicating and operating, advising or otherwise acting on patients, keeping their families informed, organizing work, teaching, and supplies, keeping the wards clean, etc.

Not every component of a social system is a social subsystem of it. Thus the persons composing a social system are biosystems not sociosystems. Nor is every subset of the membership (composition) of a social system a social system itself. For example the employees of an industrial plant and the students of a school need not be social systems. It is only when organized, and acting as a whole in certain respects (e.g. going on strike), that a bunch of persons becomes a system. *A fortiori* the working class and the student population of a society may not constitute systems.

Consider now a homogeneous set of subsystems of a given society, such as the collection of all farms, all refuse collection and disposal systems, or all schools. Such sets are not systems but *kinds* of system. An arbitrary such set will be called an F-system, where F is short for the function(s) characterizing the member subsystems in contradistinction to others. More precisely, we put forth

DEFINITION 5.4 Let σ be a human society and call

$$S(\sigma) = \{\sigma' \in \Sigma \mid \sigma' \lesssim \sigma\}$$

the collection of all social subsystems of σ. Further, let F be a certain set of social relations or transformation relations, i.e. $F \subset S \cup T$, and let

$$F(\sigma) = \{\sigma' \in S(\sigma) \mid F \subset \mathscr{S}(\sigma')\} \subset S(\sigma)$$

be the collection of subsystems of σ where the F relations hold.
Then

(i) $F(\sigma)$ is called the *F-sector* of σ;

(ii) $G(\sigma) = \bigcap_{\sigma' \in S(\sigma)} \mathscr{S}(\sigma')$ is (are) called the *generic function*(s) of the subsystems of σ;

(iii) $F_s(\sigma) = \bigcup_{\sigma' \in F(\sigma)} \mathscr{S}(\sigma') - G(\sigma)$ is (are) called the *specific function(s)* of the F-sector of σ.

To put this definition to work think, e.g., of the retail, the school, the manufacturing, and the postal sectors of a community: see Figure 5.1.

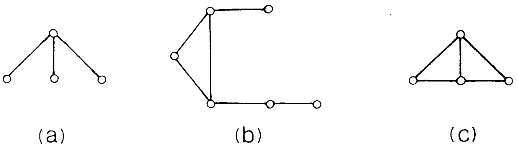

Fig. 5.1. Three sectors: (*a*) school system (connected indirectly via school board) or retail marketing system (connected indirectly via wholesale distributor); (*b*) manufacturing system (where the inputs to some subsystems are outputs to others); (*c*) postal network (controlled by central post office).

In all these cases the subsystems concerned perform certain peculiar functions that set them apart from the subsystems in other sectors; but they also share a number of functions proper to all social subsystems, such as consuming or transforming energy, producing waste products, and communicating with other subsystems of the community.

Primitive societies have relatively few sectors – e.g. the domestic work sector, the hunting sector, the manufacturing sector, the cultural sector (which is actually a system), and a few others. As society evolves some sectors become extinct while new ones emerge. Industrial societies are characterized by the large number and size of their sectors. They are also characterized by an increasing systematization of their sectors, i.e. an increasing coupling among the members of their sectors. Thus in a monopolistic economy every economic unit is a member of a tightly knit system. The general concept is elucidated by

DEFINITION 5.5 The F-sector $F(\sigma)$ of a society σ is the *F-system* of σ iff the membership of $F(\sigma)$ constitutes the composition of a subsystem of σ.

Finally we assume

POSTULATE 5.2 Every human society has a number of sectors. Moreover (*a*) every member of a human society belongs to at least two sectors of it and no individual belongs to all sectors at the same time, and (*b*) some sectors of every human society are systems.

Remark 1 In other words, there is some division of labor in every society, however primitive; yet the division of labor in human societies is never as thorough as in insect societies. *Remark 2* The above axiom, together with the epistemological postulate of knowability, entails the methodological theorem that every society can be ananalyzed into a number of sectors and, in particular, subsystems. What is nowadays called *large systems analysis* is mainly such an analysis, or recognition and characterization of the sectors and subsystems of a given society – such as, e.g., the transportation system of a city, and the marketing system of a region.

1.3. *Institution*

The word ‘institution’ is ambiguous: sometimes it denotes an individual sociosystem of a certain kind, such as a given school, and at other times it denotes a set of social actions and norms, such as marriage and religious cult. We are interested here in yet another acceptation of the word 'institution', namely the one used in speaking of the Family, the Mail, the Bureaucracy, or the Law.

Social philosophers are divided over the nature of institutions, hence over the proper way of studying them. The two classical doctrines in this field are holism and individualism. The holist regards an institution such as the Law as a disembodied corpus of rules or laws that individuals enforce, obey, or violate. According to this view the institution hovers above the persons and moreover is superior to or more valuable than them. No wonder holism, in some from or other, is inherent in totalitarian ideologies. The individualist rejects such an abstraction and regards the Law as the set of judges, lawyers and policemen – with total neglect of the subjects of the Law, namely the common citizens. When confronted with a sentence such as 'The Law compelled X to do Y', the individualist translates it into 'Judge (or policeman) U forced X to do Y'. But of course this is a poor substitute for the original sentence, as the person U in charge of enforcing the law behaves as he does because of what he is, namely a member of a certain legal system with a code of legal procedure. Different individuals might have behaved in roughly the same way. On the other hand the same individuals, in a different legal system, might behave differently. In conclusion, the legal system in question is neither the set including the individuals U and X nor a set of supraindividual rules. Hence although both holism and individualism have their points, neither is competent to account for the behavior of the individual in society. Holism fails because it postulates totalities transcending the components, and individualism fails because it ignores the totalities.

Our systemist view is as follows. A legal system is a subsystem of some society, i.e. it is a part of a human community set off by certain peculiar social relations of the M type, such as those of judging and passing sentence. And what is called 'the Law', with an awesome capital, is the collection of all legal systems. In general, we shall construe an institution as the set of all the F-sectors of all societies, regardless of their spatial and temporal propinquity. Thus the collection of all school sectors is called Education, the set of all trade unions Organized Labor, the set of all postal systems the Mail, and so on. (Recall Definition 5.4 of an F-sector and Definition 5.5 of an F-system.) We make then

DEFINITION 5.6 Let $\Sigma = \{\sigma_1, \sigma_2, \dots, \sigma_m\}$ be a set of human societies, and call F_{ik} the kth sector of society σ_i, i.e.

$$F_{ik} =_{df} = F_k(\sigma_i) = \{\sigma' \in S(\sigma_i) \mid F_k \subset \mathscr{S}(\sigma')\},$$

where F_k designates a certain set of social or of transformation relations. Then the family of F-sectors

$$\mathscr{F}_k = \{F_{ik} \mid F_{ik} \text{ is the } k\text{th sector of } \sigma_i \;\&\; \sigma_i \in \Sigma \;\&\; 1 \leq i \leq m\}$$

is called the *F-institution* of Σ.

In our construal, then, an institution is neither an individual sociosystem nor a Platonic set of rules, norms or goals governing people from above. But, since an institution is a *family of sets* of concrete things, it is tolerably abstract. (A sheer abstraction is one that, unlike an $\mathscr{F}_k$, does not boil down to concrete particulars. Sheer abstractions belong in logic and pure mathematics but are intolerable everywhere else.) To endow such a set of sets with properties of concrete individuals, such as life (or worse: an eternal life), a mind of its own (or worse: a deranged mind), aggressiveness, or the possibility of conflicting with similar types (e.g. other institutions), is to indulge in reification.

Note that not everything that passes for an institution in ordinary language qualifies as such according to our definition. For instance Work, War, Marriage, and Money do not because they are not families of sets of social subsystems.

It might be objected that our definition of an institution misses an essential ingredient, namely the goals and norms of the institution. Thus when applied to the case of the Law regarded as an institution, our convention seems to make no room for the codes of law and legal procedure that regulate the relationships at work in any legal system. The part such rules play is so important that some social philosophers and scientists have gone to the point of identifying an institution with the set of its norms or rules. This, though exaggerated and definitely Platonic, does contain a grain of truth: it is obvious that, unless certain rules are observed, the institution (or rather each of the subsystems forming it) decays or even becomes extinct. However, it does not follow that a set of institutional rules (e.g. the bylaws of an association) is an Idea dangling above the corresponding social subsystems, let alone identical with them.

The institutional rules are just the way the corresponding subsystems are thought (rightly or wrongly) to function optimally in the interest of society or of some social group. If preferred, those rules are prescriptions to operate the subsystems in an efficient manner – i.e. to attain the goals of its members, or rather of those whom the system is supposed to serve.

Undoubtedly such institutional rules can be rendered explicit for the most part, just as the rules for doing properly some job or playing some game can be formulated explicitly up to a point. But the writing down of a rule does not confer autonomous existence upon it: this may only suggest, wrongly, that it has one – perhaps because, when inscribed on a clay tablet, a stone slab, or a papyrus, it can outlast its author. The upright and merciless judge enforces rules just as the foreman has an operating manual observed.

The actions abiding by the rules of an institutional game may be called 'rule directed' as long as we do not suggest thereby the idealist thesis that rules exist independently of the rulers, the rule enforcers, and the ruled – anymore than the laws of nature are separate from the things satisfying them. The rules of social behavior are inherent in the very relationships holding among the members of the system in question. (Much the same holds for any deviations from that behavior: the delinquent may be an outlaw in the sense that he does not observe the code of law, but he is as much a member of the legal system as the judge – so much so that there is no need for a legal system where there is no occasion for delinquency.) In short the institutional rules, and also the patterns of breaking such rules and the rules for punishing these violations, are incorporated into the very network of social relationships that hold the system together. And it is not "society" that sanctions them or punishes any deviations from them, as the holist would have it, but rather some members of society, namely those in charge of regulating the functioning of the social system. By conceiving of institutional rules as patterns of the optimal or at least desired functioning of social systems, it becomes easier to understand how those rules originated, where they fail, and in what respects they could be improved upon if not repealed altogether.

So much for a preliminary conceptual framework. Let us now proceed to analyze more closely some of the typical concepts of the social sciences, starting with that of work.

2. SOCIAL SUBSYSTEMS AND SUPERSYSTEMS

2.1. *Work*

Work, one of the peculiarities of human behavior, is a kind of activity – not just an action but a regular one. An activity, whether performed by animal or by machine, may be defined as a patterned sequence of actions aiming at some preset goal. Thus, far from being erratic, an activity proceeds in such a way that, normally, the difference between attainment and target is gradually decreased (Wiener, 1948, Ch. IV). See Figure 5.2. We compress these remarks into

DEFINITION 5.7 A system performs an *activity* iff it executes a sequence of goal-directed actions.

For a system to perform an activity it is necessary and sufficient that it be a control system and that it, or whatever controls it, have a definite goal. In the case of work, the worker himself, together with his tools, constitutes a control system.

Unlike machines, humans are versatile or multipurpose systems: they can perform activities of very many kinds. This multiplicity can be represented as follows. Call ${}^{\sigma}A_{mn}$ the action performed by system σ on the *m*th aspect (property) of the *n*th thing in the environment of σ. Then the total activity of σ is displayed by its activity matrix ${}^{\sigma}A = \|{}^{\sigma}A_{mn}\|$. This is an $M \times N$ matrix, where M is the number of properties and N the number of things influenced by σ. An empty entry corresponds to a nonexisting feature of the corresponding thing. If an entire community, or a sector of it, with membership S, is engaged in a set of activities, we may define the aggregate activity of the community or sector as the matrix

$$A = \bigcup_{x \in S} {}^{x}A,$$

every entry of which is the set theoretic union of the partial entries with the same indices.

Work is a special kind of activity, namely one thought to be useful. We define it as follows:

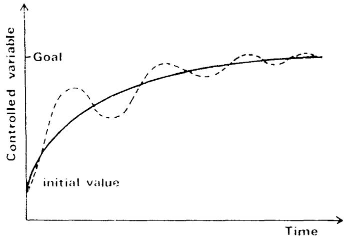

Fig. 5.2. A system attaining asymptotically a goal state in either of two typical ways: (*a*) monotonically (full line) or (*b*) by trial and error (dotted line). Note in the latter case the phenomenon of overshooting (momentarily overreaching the goal).

DEFINITION 5.8 If x is a system, then x *works* iff there exists a thing y and an animal z (equal to or different from x) such that

(i) x exerts an activity on y (in a way other than by eating y) and by so doing produces an appreciable change in the state of y, and

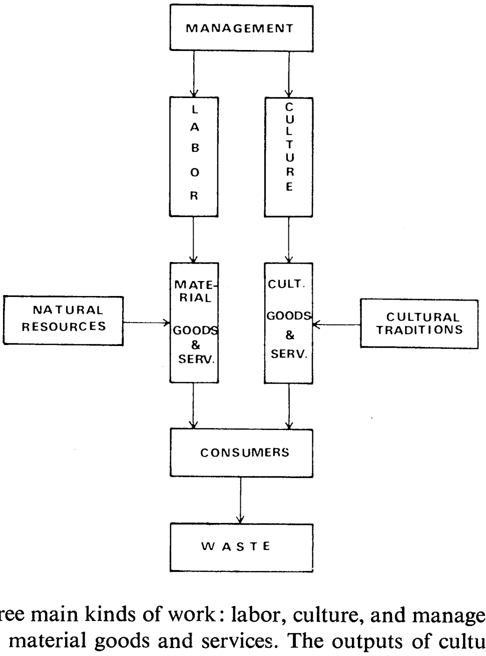
(ii) the thing y in the new state brought about by the activity of x is of value to z.

We distinguish three kinds of work, namely labor (L), cultural work (K), and managing (M). Labor aims at transforming nonhuman things into more valuable things; cultural work aims ultimately at modifying brain functions; and managing consists in controlling both labor and cultural work. See Figure 5.3. Let us first examine labor.

2.2. *Labor*

We start off by making

DEFINITION 5.9 Let σ be a society with composition $\mathscr{C}(\sigma)$, environment



MANAGEMENT
LABOR
CULTURE
NATURAL RESOURCES
MATERIAL GOODS & SERV.
CULT. GOODS & SERV.
CULTURAL TRADITIONS
CONSUMERS
WASTE

Fig. 5.3. The three main kinds of work: labor, culture, and management of both. The outputs of labor: material goods and services. The outputs of cultural work: cultural goods (e.g. books) and services (e.g. education).

$\mathscr{E}(\sigma)$, and structure $\mathscr{S}(\sigma) = S \cup T$, and call L a subset of the transformation relations in σ. Then

(i) the element $L_i \in L$, with $1 \leq i \leq r$, is called the ith kind of *labor*, or *primary work*, done by members of σ, iff L_i is an activity performed on nonhuman things, the outcome of which is a set of things or a change of state in things, that is valuable to members of σ;

(ii) the domain of L_i is $(\mathscr{C}(\sigma))^p \times (\mathscr{E}(\sigma))^q$, where $p, q \geq 1$, and the range $A_i \subset \mathscr{E}(\sigma)$ of L_i is called the *product* of L_i, and each element of A_i an *artifact*;

(iii) the totality of products [goods and services] of the labor performed in σ, i.e. $\mathscr{A}(\sigma) = \bigcup_i A_i$, is called the *material production* of σ, whereas the complement $\mathscr{N}(\sigma) = \mathscr{E}(\sigma) - \mathscr{A}(\sigma)$ of $\mathscr{A}(\sigma)$ to the environment of σ is called the *natural environment* of σ;

(iv) the subset ${}^1P_i \subset \mathscr{C}(\sigma)$ occurring in the domain of the labor-relation L_i is called the set of *primary producers* of A_i, or the ith *labor force* of σ;

(v) the union ${}^1P = \bigcup_i {}^1P_i$ of primary producers of σ is the *labor force* or *primary manpower* of σ.

Remark 1 Our definition includes not only the production of material goods but also the performance of services. *Remark 2* It is not implied that labor be manual: it may well consist in controlling automated machinery. *Remark 3* Our concept of labor or primary work does not coincide with the standard concept of primary industry: the primary producers or laborers referred to above may be hunters or fishermen, farmers or industrial workers, miners or carpenters or repairmen. *Remark 4* Nor does our concept of an artifact coincide with the popular one: it is a technical one. Thus domestic bacteria, such as those used to make butter and cheese, as well as cultivated plants and domesticated animals, being products of artificial selection, are artifacts in our sense of the word. Machines are only a very special kind of artifact.

The set $L = \{L_i \mid 1 \leq i \leq r\}$ of kinds of labor cannot be empty for any society, under penalty of extinction. It may happen that a community subsists for a time on spoils of some kind, but even the most bountiful spoils of war become exhausted after a while. Moreover the set L must contain more than one member, for each kind of labor 'leads to' other kinds. Thus felling trees is done to employ timber for one or more purposes (activities), and it cannot be done efficiently, except by beavers, without axes or saws – which have to be manufactured. We compress these remarks into

POSTULATE 5.3 In any human society

(i) there is more than one kind of primary work, i.e. $| L | > 1$;

(ii) there are workers engaged (permanently or temporarily, exclusively or not) in every kind of work done in the society, i.e. $P_i \neq \varnothing$ for every $1 \leq i \leq r$.

Finally we make

DEFINITION 5.10 Let $\mathscr{E}(\sigma) = \mathscr{N}(\sigma) \cup \mathscr{A}(\sigma)$ be the immediate environment of a society with labor force ${}^1P$ and labor (primary work) relations in L. Then the *material force of production* of σ is the ordered triple $\langle {}^1P, \mathscr{N} \cup \mathscr{A}, L \rangle$.

Should any coordinate of this triple be empty, there would be no material force of production. In particular, an inactive (unemployed) labor force is as ineffectual as a nonexisting stock of natural resources. However, a scarcity in the latter can be compensated for by material production thanks to exchange. But someone, in some society or other, has got to produce food: there is no such thing as a postagricultural world society. Likewise there is no postindustrial society but only one in which most of the labor force is engaged in performing services rather than in agricultural or industrial work. No labor, no human society.

Let us move on to the other components of the manpower of any human society.

2.3. *Cultural and Managerial Work*

Let us now characterize the kind of work done by artists, bards, composers, performers, actors, story tellers, writers, teachers, scholars, scientists, engineers, and physicians of all descriptions, whether competent or not:

DEFINITION 5.11 Let σ be a society with composition $\mathscr{C}(\sigma)$ and social relations in S, and call $K \subset \mathscr{S}(\sigma)$ a proper subset of the social structure of σ. Then

(i) the element K_j of K, for $1 \leq j \leq s$, is called the *j*th kind of *cultural* (or *secondary*) work done by members of σ iff K_j is an activity capable of evoking feelings or thoughts, or supplying ideas intervening in the primary production of σ;

(ii) the subset ${}^2P_j \subset \mathscr{C}(\sigma)$ occurring in the domain of the cultural work relation K_j, is called the *j*th set of *cultural* (or *secondary*) producers of σ;

(iii) the union ${}^2P = \bigcup_j {}^2P_j$ is called the *cultural* (or *secondary*) *manpower* of σ.

Remark 1 Although cultural work aims at changing the way people feel or think, K is not disjoint from T. Indeed, all cultural work involves transforming some thing or other, if only the state of the surrounding air. Moreover there are useful works of art, such as artistically designed pieces of furniture, as well as useful works of science, such as scientifically controlled instruments. *Remark 2* According to clause (i), writing a book that may be published is doing a spot of cultural work; even writing or performing a piece of rock "music" is perpetrating some cultural work. Not so engaging in praying, dreaming, or transcendental meditation – which is sleeping anyhow. Likewise drawing the blueprint for a house or a machine or the pattern for a dress is engaging in cultural work, whereas drawing exclusively for one's pleasure, or humming a melody, are not. To be cultural an activity must be social or socializable as well as artistic or intellectual.

We shall return to the matter of cultural work in Sec.3.2. Let us now characterize the relations aimed at influencing social behavior in an immediate way, rather than through the subtle medium of culture:

DEFINITION 5.12 Let $M \subset S$ be a subset of the social relations in a human society σ. Then

(i) the element $M_k \in M$ is called the kth kind of *managerial* (or *organizing* or *tertiary*) *work* done by members of σ iff M_k is an activity contributing to controlling some primary or secondary work done in σ;

(ii) the subset ${}^3P_k \subset \mathscr{C}(\sigma)$, for $k = 1, 2, \ldots, t$, occurring in the domain of the managerial relation M_k, is called the kth set of *tertiary* (*managerial, organizing*) *workers* of σ;

(iii) the union ${}^3P = \bigcup_k {}^3P_k$ is called the *managerial force* (or *tertiary manpower*) of σ;

(iv) the subset ${}^3P_L$ of P^3 devoted to controlling the primary production of σ is called the *production management* of σ, and its complement ${}^3P_k = {}^3P - {}^3P_L$ the *culture management* of σ.

In other words, we call *managerial* all the kinds of work aimed at controlling production, whether agricultural or artistic, industrial or intellectual. Planners, plant managers, executives, members of socialist farm or factory councils, commune leaders, judges, bureaucrats, censors, and in general decision makers and transmitters of all kinds belong to management as construed above. Moreover one and the same individual may belong to two or more manpowers, as is often the case in primitive societies.

We assume

POSTULATE 5.4 Every human society has both a cultural manpower (i.e. ${}^2P \neq \varnothing$) and a managerial one (i.e. ${}^3P \neq \varnothing$).

From this platitude it follows that, under risk of destroying society, it is impossible to do entirely without either the cultural force or the managerial force. What one should aim for is maximizing the harmonious cooperation among all three work forces, i.e. easing the tensions and therefore eliminating the need for keeping repression forces. In particular, rather than try quixotically to eliminate management one should strive to make it work in the interest of material and cultural production rather than in its own interest. Such a blending of management with productive forces obtains in a well run modern industrial plant, marketing system, communications network, hospital, or school – in short wherever some people work according to the canons of advanced (scientific) technology. Such sociosystems deserve a name of their own:

DEFINITION 5.13 A system τ is a *technosystem* iff

(i) the composition of τ includes rational beings and artifacts;

(ii) the environment of τ includes components of a society;

(iii) the structure of τ includes production, maintenance or use of artifacts.

A modern American household full of gadgets does not qualify as a technosystem unless it is the seat of a family concern where intellectual work plays a significant role. On the other hand a modern defense system is a technosystem, for military experts are supposed to do some intellectual work as part of their duty.

The composition or population of any human society is made up of an active part – those who do work of some kind – and an inactive one. All those persons – housewives, shepherds, fishermen, hunters, craftsmen, industrial workers, white collar workers, physicians, engineers, poets, musicians, philosophers, etc. – who participate in the transformation of raw materials into artifacts, do artistic or intellectual work, or take part in organizing material or cultural production of goods or services, make up the active population or human resources. In short, we have

DEFINITION 5.14 Let σ be a human society. Then

(i) the *active population*, or *human resources*, of σ is the union of its manpowers: $A = {}^1P \cup {}^2P \cup {}^3P$;

(ii) the *inactive population* of σ is the complement of A to the membership of σ, i.e. $I = \mathscr{C}(\sigma) - A$.

2.4. *The Main Subsystems of a Human Society*

Neither the active population nor the inactive one constitute systems; nor are the subsets ${}^1P$, ${}^2P$, and ${}^3P$ systems. Thus the managerial force of a society is hardly a system: managers are components of either the economic, the cultural, or the political systems of a society. Each of these systems draws its components from all three manpowers: see Figure 5.4. Thus industry, trade and government employ artists, intellectuals and professionals of various descriptions; and both manual and clerical workers take part as auxiliaries in cultural production as well as in political management. We have then the division

$$ {}^iP = {}^iP_L \cup {}^iP_K \cup {}^iP_G \quad \text{for} \quad i = 1, 2, 3 $$

of each manpower into one part engaged in primary production, another engaged in cultural production, and another engaged in political control. Whereas the upper index i identifies the specific output of the sector, the lower indices name its various inputs.

Correspondingly we distinguish certain subsets of the collection S of social relations: we call S_L, S_K, and S_G respectively the social relations associated with primary production, cultural production, and political administration. Finally, we group similarly the work relations: we call

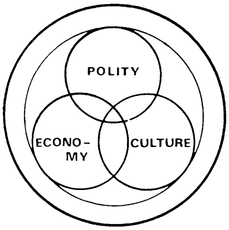


Fig. 5.4. The main subsystems of any society. Outer circle: whole society. Inner concentric circle: kinship system. Eccentric circles: *economy* (gathering, hunting, fishing, manufacturing, trading, financing); *culture* (artistic, technological, scientific, humanistic creation and their diffusion); and *polity* (government of all kinds, nongovernmental political activity, and the military). The overlaps suggest that some persons participate in two or even three systems. E.g. a scientist belongs to the cultural system by virtue of his research and teaching; to the economic system if he writes textbooks; and to the political system if he acts as consultant to the government.

L_K and L_G repectively the kinds of primary work done in cultural production and in government by members of the labor force; K_L and K_G the kinds of cultural work involved in primary production and in politics respectively; and M_L, M_K and M_G the kinds of management involved in primary production, cultural production, and politics respectively. We are now ready for

DEFINITION 5.15 Let σ be a society with labor force ${}^1P$, cultural force ${}^2P$, and managerial force ${}^3P$. Further, let the subscripts L, K and G identify whatever is associated with primary production, cultural production, and political administration respectively. Then

(i) the subsystem of σ represented by

$$\varepsilon_\sigma = \langle {}^1P_L \cup {}^2P_L \cup {}^3P_L, \mathscr{E}(\sigma), S_L \cup (L \cup K_L \cup M_L)\rangle$$

is the *economy* (or *economic system*) of σ;

(ii) the subsystem of σ represented by

$$\kappa_\sigma = \langle {}^1P_K \cup {}^2P_K \cup {}^3P_K, \quad \mathscr{E}(\sigma), S_K \cup (L_K \cup K \cup M_K)\rangle$$

is the *culture* (or *cultural system*) of σ;

(iii) the subsystem of σ represented by

$$\pi_\sigma = \langle {}^1P_G \cup {}^2P_G \cup {}^3P_G, \mathscr{E}(\sigma), S_G \cup (L_G \cup K_G \cup M_G)\rangle$$

is the *polity* (or *political system*) of σ;

(iv) ε_σ, κ_σ, and π_σ are the *artificial* main subsystems of σ.

The previous definition allows us to restate Postulate 4.26 in a more complete way:

POSTULATE 5.5 (i) Every human society is composed of four subsystems: the kinship, the economic, the cultural, and the political systems; (ii) every sociosystem in a human society is part of at least one of its four main subsystems; (iii) every individual in a society belongs to the composition of at least one of the four main subsystems of the society.

Remark 1 By conceiving of the economy, the culture and the polity as systems, one avoids the sterile philosophies of holism and of individualism. For the same reason one obtains the possibiity of modeling the entire economy (or culture or polity) of a society as a system with definite composition and structure – provided one includes in the latter the links of the economy (or the culture or the polity) with the other subsystems. *Remark 2* All three artificial subsystems share the same natural and artificial environment; in particular no culture and no polity can function in a physical vacuum. Hence extreme internalism (e.g. cultural idealism) is just as inadequate as extreme externalism (e.g. ecological or geographic determinism). *Remark 3* Each manpower is distributed among the three artificial subsystems. In particular, not even the most primitive economic system fails to employ some cultural workers and some organizers – even if they are at the same time primary producers – and not even the most anti-intellectual of political systems dispenses altogether with intellectuals, e.g. as planners and censors. *Remark 4* It is possible for one and the same individual to belong to more than one of the main subsystems. It is impossible for an individual to fail to belong to at least one of the main subsystems – i.e. complete marginality is impossible within a society. *Remark 5* A significant change in any of the three coordinates of each subsystem (membership, environment, structure) will affect the system as a whole. Examples: an increase, or decrease, in the percentage of skilled workers or of intellectuals; an increase, or decrease, in the consumption of energy *per capita*. When the change is both drastic and fast, it is called a *crisis* – of growth or of decline. *Remark 6* Because each of the three artificial subsystems is a subsystem of the same society, it is linked to the other two. Such couplings would be impossible if the systems in question (the economy, the culture, and the polity) were sets of individuals (individualism) or Platonic ideas (idealistic holism). *Remark 7* Disregarding or even minimizing the importance of any of the four main subsystems of a society leads to lopsided views, hence inadequate doctrines of political action. The same holds for neglect of the interactions among the subsystems.

2.5. *The Supersystems: Nation and World*

We regard a *nation* as a social system, or rather supersystem, composed of all the kinship, economic, cultural, and political systems coexisting and interacting within a territory. Unlike the city-states of Antiquity, modern nations are composed of several societies, each of which occupies a given geographical region within the national territory (which need not be in one piece). Each component society contributes its own kinship, economic, cultural, and political subsystem to the whole. The artificial subsystems are coupled to one another forming a national economy, a national cultural system, and a political system. None of these national systems need be homogeneous: on the contrary, variety makes for viability. (The ideology according to which homogeneity is a supreme desideratum is called *nationalism*, and is particularly vociferous in demanding racial purity, cultural homogeneity – i.e. poverty – and political uniformity – i.e. dictatorship.) If the integration among the various societies composing a nation is weak, then the nation is so only in name, as was the case with the Holy Roman Empire most of the time. If the integration is too strong, then the nation is cut off from other nations. The best coupling strength is middling.

The relations among or within the three main artificial subsystems of a nation are of the following kinds: (*a*) economic – e.g. society *X*'s supplying energy to society *Y*; (*b*) economicocultural – e.g. research scientists's developing a new variety of wheat; (*c*) economicopolitical (e.g. an economic group's lobbying for a bill favoring its interests); (*d*) cultural (e.g. intercity library loans); (*e*) politicocultural (e.g. a governmental agency's encouraging or obstructing technological innovation); (*f*) political (e.g. the armed forces seizing control of certain governmental agencies).

All of these relations are intersystemic. Yet in the final analysis they rest on person to person relationships, where the persons concerned act out their social roles. Thus when analyzing a social relation *S* between two subsystems of a nation we may ultimately explain *S* in a way such as this: System *b* bears relation *S* to system *c* if and only if there is an individual compoment *x* of *b* and an individual component *y* of *c*, such that *x* bears *S* to *y*, where *S* is an inter personal bond such as, e.g. writing a note asking for some item of property on loan. (Clearly the individuals concerned may be represented by robots, but the latter are built to act not in their own interest but in that of their master.) In other words, the relations in a supersystem such as a nation can be analyzed, at least in principle, in terms of interpersonal relations, as long as the roles of the persons are identified – roles which are not further reducible to properties of isolated persons. If such roles and the associated responsibilities are forgotten, i.e. if societal relations are mistaken for private relations, not only a faulty analysis results but a law may be broken. In short, although every social system is ultimately composed of individuals, these happen to engage in relations that are incomprehensible without the hypothesis that the system has supraindividual properties. (Recall Definition 5.2.)

Economists, sociologists, politologists, and social historians are becoming increasingly interested in whole regional blocs and international systems, thus recognizing that the nation is often either a subsystem or a supersystem, and in either case an inadequate unit of study. (The model for social history is Braudel's *La Méditerranée* (1949). A recent addition to the systemist approach is Wallerstein's *The Modern World-System* (1974).) Indeed there are no isolated nations left it there ever were. Every modern nation bears economic, cultural or political relations to other nations, and this on four levels: person to person, subsystem to subsystem, nation to nation, and international organization to international organization. (It goes without saying that all system to system relations are designed and implemented by individuals. However, these individuals can often be replaced by others enacting the same roles or functions. Not that their personalities are unimportat; only, these serve or disserve their roles or functions.) Let us take a quick look at international relations. (Cf. Deutsch, 1968; Fritsch, 1974; Bunge *et al.*, Eds., 1977.)

In addition to some 150 nations there are today about 10,000 international organizations. The latter include (*a*) international governmental organizations such as the World Health Organization, (*b*) international nongovernmental organizations such as the International Union for the History and Philosophy of Science, and (*c*) multinational corporations such as the General Motors Co. Since every other social system is either a subsystem of some international organizations or closely related to some of them, it would be utopian to plan anything on a national scale without taking the international context into account. This context is the *international system*, composed by all nations and all international organizations; its environment is no less than the biosphere; and its structure the set of relations (economic, cultural, political, economicopolitical, politicocultural, etc.) among its various components. These relations are rather entangled. For example, nation A trades with nation B and has close political ties with nation C, a rival of B; consequently the trade relations are affected by the political ones and reciprocally. Politologists tend to say that this is a case of relations among relations or cross relations. Since this notion is fuzzy, we prefer to analyze the same facts using our systemic framework, namely as follows.

Every international actor (nation, intergovernmental organization, multinational corporation, etc.) has three chief subsystems, every one of which can interact with any of the subsystems of the other two. See Figure 5.5. By completing this diagram we realize that two members of the international system can engage in 9 *sets* of binary relations, to wit: $E_1 - E_2$, $E_1 - C_2$, $E_1 - P_2$, $C_1 - E_2$, $C_1 - C_2$, $C_1 - P_2$, $P_1 - E_2$, $P_1 - C_2$, $P_1 - P_2$. For n members of the supersystem, the total number of sets of binary international relations is $N = (9/2)n \cdot (n - 1)$. For the entire interna-

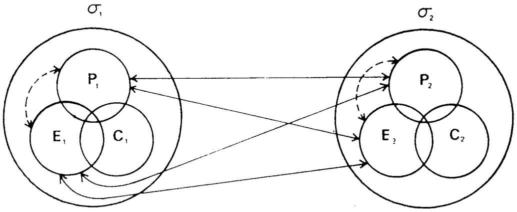

Fig. 5.5. Example of international economic and political relations between two nations σ_1 and σ_2. Note the two intranational relations besides the four international ones: the former are indicated by dotted lines.

tional system today, $n \cong 10{,}000$, whence $N \cong 450$ million sets of international relations. (The number computed on the assumption of the ghostly relations among relations is far more staggering, namely of the order of 10^{15}, or 7 orders of magnitude greater than ours.) This is a forbidding figure yet still modest by comparison with the number of pairwise relations among the atoms in a wedding ring, namely 10^{38}. The politologist can get around this hurdle just the way the physicist does, namely by taking into account only the relations among nearest neighbors. In this way whole blocs emerge, and then the relations among blocs can be studied – just as with any other supersystem analyzed into lower level subsystems. Such a systems analysis paves the way to the construction of theoretical (mathematical) models including precise functional relations among the variables. (Cf. Bunge, 1977h.)

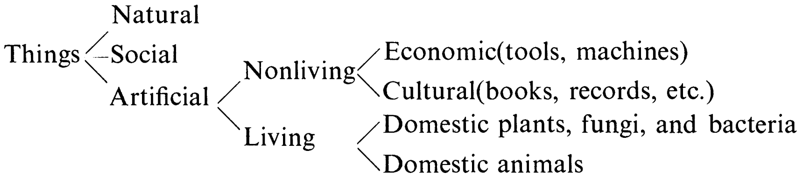
So much for a preliminary study of the main subsystems and supersystems of human society. Let us now take a closer look at each of the three artificial subsystems of every society.

3. ECONOMY, CULTURE, AND POLITY

3.1. *The Economic System*

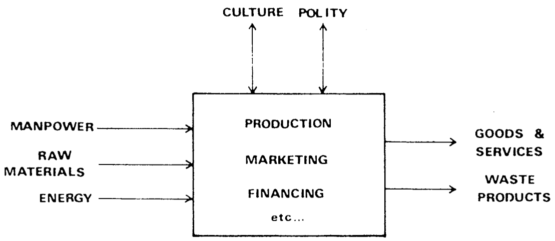
According to Definition 5.15 the economic system of a society is composed of its primary workers (${}^1P_L$), cultural workers (${}^2P_L$), and managerial workers (${}^3P_L$). The primary workers are engaged in primary production (L), the cultural workers are in charge of the cultural input to primary production (K_L), and the managerial workers organize both (M_L). Thus the machinists, electricians, truck drivers and maintenance workers of an industrial plant belong to ${}^1P_L$; the engineers, quality controllers and draughtsmen, to ^2P_L; the executives, accountants and typists, to ^3P_L; the foremen often belong to all three sets but their specific function is as members of ^3P_L. All these workers share the same environment and bear (production) relations S_L among themselves in addition to whatever other relations they may hold. The input–output schema of an economic system is shown in Figure 5.6.

Of all the aspects of the economic system, those of greatest philosophical interest are perhaps technology and the artifacts it produces and employs. Both raise numerous philosophical problems of all kinds, hardly investigated (cf. Bunge, 1977g). Let us say a word or two about artifacts, i.e. things fashioned by rational beings with the help of some technique, whether primitive or advanced. An artifact is not just one more thing but a thing belonging to a kind that did not exist before the emergence of man or some other rational being. Artifacts may be regarded as constituting a whole new level of reality, namely the *artiphysis*. The set of all concrete things may now be classed as follows:



Things
Natural
Social
Artificial
Nonliving
Economic(tools, machines)
Cultural(books, records, etc.)
Living
Domestic plants, fungi, and bacteria
Domestic animals

Far from being contemptible entities whereof a philosopher does not deign to speak, artifacts are at the heart of human society and have properties absent from natural things. To understand this point it may help to



CULTURE
POLITY
MANPOWER
RAW MATERIALS
ENERGY
PRODUCTION
MARKETING
FINANCING
etc...
GOODS & SERVICES
WASTE PRODUCTS

Fig. 5.6. Schema of the economic system. Inputs: natural resources (raw materials and energy) and human resources. Outputs: goods, services, and waste products. Some of the outputs are fed back into the system (e.g. as tools). Controls: culture (mainly techniques and advanced technology), and politics.

recall the various items entering the production, servicing, use, and circulation of artifacts. They are chiefly the following: (*a*) the idea or design of the artifacts; (*b*) the idea of the possible use(s) of the artifact; (*c*) a plan or design for the manufacture of the artifact; (*d*) the raw material and the energy required to produce the artifact, (*e*) the actual production process; (*f*) the marketing of the finished product; (*g*) the control of the entire process. Of all these seven ingredients only one, the fourth, is supplied by nature. Because all the others are ultimately in the hands or brains of people, the artiphysis is totally at their mercy. Men, or similar social animals, create it and can destroy it. Artifacts have no will of their own and, indeed, no existence of their own: even the most sophisticated among them are but tools. And technology has no autonomy either: it is cultivated only in societies that care for it. A band of technoclasts could kill every technologist and destroy every artifact on Earth in a few days. So, to claim that technology and the set of artifacts have a life and a momentum of their own, that they cannot be stopped, is bizarre to say the least.

We summarize the foregoing in

POSTULATE 5.6 (i) Every human society has members able to design, manufacture, repair, or use artifacts; (ii) every nonliving artifact [tool or machine] serves only the purpose(s) of some animal or other.

It follows that no machine, not even a highly evolved robot, has a purpose of its own: whatever the goal seeking mechanisms built into it, they have been designed and ultimately manufactured by rational beings in their own interests. Hence machines stand no chance of taking over unless of course programmed to do so. It follows also that, when a nonliving artifact imitates rational animals in certain regards, it does so by proxy not spontaneously. A further consequence is that artifacts can neither evaluate nor think on their own. That they do not evaluate is obvious since they have no goals other than those built into them by their designers. (This vicarious evaluation capacity may reside in the hardware, as when a machine is designed to seek or to avoid certain stimuli or else to rank them. Or in the software, as when a machine is programmed to weigh apples or alternative routes for mail delivery. In either case delegated evaluation may trigger a vicarious decision – e.g. that of discarding an underweight apple or an inconvenient route. When speaking of 'the vicarious abilities of machines' the technologist underlines 'abilities' whereas the philosopher emphasizes 'vicarious' – unless of course he takes the former's word.)

As for our claim that machines cannot think, it is quite obvious in the light of the psychobiological view on thought as an activity of certain neural systems (Definition 4.35). Here again machines, unlike rational beings, have no purposes – in particular cognitive goals – of their own, so they can properly be said to act by delegation. Surely machines can help us solve certain problems, but they cannot discover any because formulating a problem is not a rule directed activity and, as long as we do not master a rule, we cannot design or program a computer to follow such a rule. (This is also why there can be no self-programming machines: if a machine were to have problems of its own we would quickly scrap it.) Also, machines can be used to process the assumptions of certain theories, but they do not help create them – again for the same reason, namely because theory construction is not a rule directed activity but a thoroughly creative one. In short tools, however marvelous, are nothing but tools.

3.2. *The Cultural System*

In Definition 5.15 we characterized the cultural system of a society as being composed not only of cultural workers (${}^2P_K$) but also of primary workers (${}^1P_K$) and managerial workers (${}^3P_K$). The former are of course in charge of cultural production (K), whereas the other two groups are attached to them either in an ancillary capacity, as in the case of the maintenance workers at a university, or as organizers, as in the case of university administrators. Another example: the technicians and the typists working for an experimental biologist belong in ${}^1P_K$, while the director of the scientist's laboratory is in ${}^3P_K$, and occasionally also in ${}^2P_K$.

All the members of a cultural system share the same environment and are linked by certain relations S_K. But not all of the ingredients of a cultural system are on the same footing. Its pivots are: (*a*) the workers engaged in direct cultural pursuits, i.e. ${}^2P_K$; (*b*) the part of the natural or social environment that is the object of contemplation, study or rational action; (*c*) the part of the stock of artifacts composed of cultural artifacts such as pictures, books, microscopes, and the like, and (*d*) cultural work proper – e.g. research, writing, and instructing.

Ours is a restricted concept of a cultural system. A wider concept includes the entire cultural force of the society, i.e. not only the persons working for the sake of culture but also those engaged in an auxiliary capacity by the economic and political systems, such as the technologists in a quality control unit or the sociologists in a census bureau. However, this cultural supersystem is much less tightly knit or integrated. Thus the chemical engineer working in an oil refinery is more strongly attached to the economic system than to the cultural system *stricto sensu* – unless of course he is a research chemist, in which case he will belong to both the economic and the cultural systems, and may accordingly be torn by a conflict of loyalties. In either case the input–output schema of the cultural system is sketched in Figure 5.7.

This schema serves as a reminder that, whether in the narrow or in the comprehensive construal, a cultural system is a *concrete* system – not just "a body of meanings, values and rules". More precisely, a culture is a concrete system composed of living rational beings engaged in activities of various kinds, some of which go beyond the call of biological need, and all of which are social because they draw from tradition and influence social behavior. I.e. the creation and the diffusion of culture are social processes, shaped by society and in turn having an influence on the economy and the polity.

Our concept of a culture as a concrete system is at variance with the idealistic notion of a disembodied system of ideas, values, and rules, which is the concept favored by most anthropologists. Actually this other notion is that of a *type* of culture rather than of a particular culture. Thus where a cultural system (in our sense) includes certain actions, such as writing and inventing, a culture in the anthropological sense includes only the patterns of such actions – e.g. the rules that are supposed to regulate those actions. Nor does our concept of culture coincide with that of an ideal superstructure – made up of ideas, values, and norms – mounted on the material structure (economy and polity). Unlike these dualistic concepts of culture, ours is monistic.

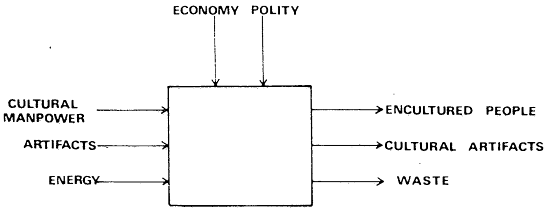


Fig. 5.7. Input-output model of the cultural system. Inputs: manpower (pivotal and auxiliary), artifacts (paint brushes, paper, pencils, books, archives, etc.), and energy (light, heat, etc.). Outputs: cultural artifacts (musical scores, sculptures, journals, etc.), people transformed by the latter, and waste products. Some of the outputs are fed back into the system. Controls: economy and polity.

The cultural systems of primitive societies are at least as monolithic as their economic and political systems, in the sense that they are not composed of subsystems. The emergence of civilization was accompanied by an explosion in the division of work, in particular cultural work. The single shaman was succeeded by a cohort of healers, priests, bards, teachers, painters, and later on skilled craftsmen and even scribes. Accordingly the cultural system split into a number of subsystems or subcultures – the religious system (centered around temples), the educational system (centered around schools), and so on. These various subcultures complement one another in certain respects but are at odds in others, if only because they all compete for a finite number of people as well as for a finite amount of material resources. In any case they interact. The mutual actions among the main subsystem of contemporary culture are shown in Figure 5.8.

Both the internal mechanisms of each cultural subsystem and its interactions with other members of the cultural system drive its changes, however slight and slow. The successive states of a cultural system constitute the *cultural evolution* (or *history*) of the society concerned. Cultural evolution modulates biological evolution and both proceed by selection. But, unlike biological evolution, cultural evolution is not purposeless. Cultural innovation and diffusion, be it technical or artistic, scientific or ideological, is partly random, partly deliberate.

A flourishing culture is one that teems with newness – valuable newness

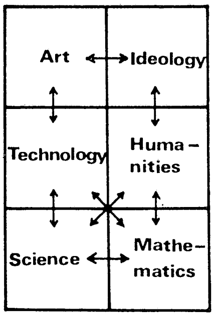

Fig. 5.8. The contemporary cultural system and its subsystems. Each box represents both creation and diffusion. The arrows represent both information flows and controls. Art and ideology, which have the most numerous memberships in traditional societies, have the fewest information links with the remaining subcultures. (From Bunge, 1977g.)

not just oddity – and is free to develop it without too much interference from the economic and political systems. A declining culture is one that ceases to value discovery and invention, and takes refuge in lamaistic repetition or in withdrawal from reality. The management of a cultural system – the politics of culture – can encourage creativity, channel it, or nip every creative bud. A dead culture is still a culture and one that can remain in that state for a long time. But because of the functional relationships among the three main artificial subsystems of every society, any major change in the economy or in the polity is bound to have cultural repercussions.

The cultural system, then, coevolves with the economic and political systems. However, the modes of evolution of these subsystems may be quite different, and neither is merely an image of the other. Thus cultural growth is compatible with zero economic growth and political stagnation, provided the political system does not interfere destructively with cultural evolution. Moreover, while economic development is limited by natural resources, there are no such limits to cultural growth: the more we know the more fresh problems we can pose and solve.

Yet there are of course economic and political constraints on cultural evolution. For one thing any given society can support only so many professional composers, mathematicians, philosophers, and so on. But at least here, unlike the case of the economy, a solution is in sight, namely automation and the amateur pursuit of cultural interests. In fact the former is freeing many hands and brains from routine work, and the good society should turn that added freedom into leisure and creation instead of unemployment. A revaluation of culture should encourage people to engage in cultural work for the fun of it rather than primarily as a source of income. Everyone should be able to master whatever cultural skill he or she likes, and to practice it during the increasingly long leisure hours rendered possible by automation. This need not encourage substandard cultural production. On the contrary, it is the increasing substitution of extrinsic motivation (pay, promotion, fame) for intrinsic motivation that is lowering the quality of cultural work. (For the negative effects of extrinsic rewards on children see Lepper *et al.*, 1973.)

To conclude. Our view of culture is at variance with idealism ("The spirit is the driving force") as well as with economism ("Culture is but a byproduct of the economy"). If every culture is a subsystem of a society then it has its own dynamics, hence some degree of autonomy, and it also interacts with the other subsystems, namely the economy and the polity.

Therefore it is neither totally free and omnipotent nor totally enslaved and powerless. Just as some members of the economic system exercise economic power, and some members of the political system wield political power, so some members of the cultural system exercise cultural power, particularly if they are entrenched in certain cultural subsystems, whether private or governmental. For example, the school system of a community exerts some cultural influence on all the inhabitants of the community – often as strong an influence as that exerted in the past by organized religion. This influence is not restricted to purely cultural matters. A creative cultural organization may study, discuss, and even propose and circulate blueprints for economic and political action. Such proposals do not amount to action but may arouse and guide it. After all people are being moved by thinking individuals all the time. Why let obsolete ideologies do all the pushing when it is possible to draw rational and feasible blueprints – i.e. to ground social action on the social sciences?

3.3. *The Political System*

The political system of a society is the subsystem of the latter that controls (to some extent) economic and cultural work as well as other types of social behavior. This control is ultimately exercised by individuals (political leaders and bureaucrats) in the interests of a few or of the majority, arbitrarily or according to rule. There is no such thing as "a government of laws, not of men" – the modern substitute for the fiction of government in the name of a deity.

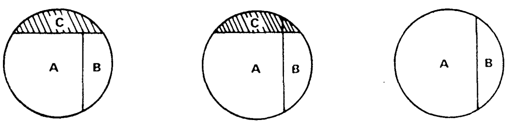
Since even infants are affected by certain political actions, one might regard the entire population of a society as composing its political body. However, for practical reasons it is convenient to restrict the composition of the political system to its actors or active members, namely the citizens with political rights or responsibilities: all others are politically marginal or passive. The structure of a political system is of course the set of social relations among the political actors, such that effect a political control. Every political *regime* (e.g. parliamentary democracy) is characterized by certain types of political relations.

The political system of a modern society, unlike that of a primitive society, has a distinguished subsystem, namely the *state* or *government*. In turn, the state of an advanced society may be analyzed into a number of subsystems, such as the defense system, the health system, the educational system, and so on. Some such subsystems constitute a relatively hard core ("technical", "nonpolitical", nonideological) that remains nearly invariant under changes in political leadership. For better or worse many such a governmental subsystem grows and strengthens to the point where it escapes almost all control. If it possesses physical force, as is the case with the army and the police, it may end up by controlling the entire political system and, through it, the whole society.

The differences among political regimes are differences in the distribution of political power, i.e. in the participation in political action. Consider a community formed by three social groups to be called A, B, and C. Assume further that A and B are mutually disjoint and that C is the political control group. Moreover all the C's have effective control: they cannot be outvoted on every important issue. Under these conditions there are exactly three possibilities: see Figure 5.9. The left circle illustrates the case of aristocratic (or theocratic) government, where the control class does not mesh with the other groups. The middle circle illustrates the various kinds of democracy (representative, participatory, etc.). The right circle illustrates anarchy: no control proper. The degrees or measures of the participation of A's and B's in C are respectively

$$\alpha = |A \cap C| / |C|, \qquad \beta = |B \cap C| / |C|.$$

In addition to such objective measures of political control, the politologist is interested in the manner in which the political system is "perceived" by people. That is, politics is not only a matter of objective political structure and power but also one of social psychology. This was seen by the founder of political science, in particular when he remarked that rebellions are caused either by the desire for equality or the desire for superiority (Aristotle, *Politica*, Bk. V, Ch. 2). Likewise Marx emphasized the



Nil participation:
No A's or B's participate in C:
$A \cap C = B \cap C = \emptyset$
$\alpha = \beta = 0$.

Partial participation
Some A's and B's participate in C:
$A \cap C \subset A, B \cap C \subset B$
$0 < \alpha, \beta < 1$.

Full participation
All A's and B's participate in C:
$C = A \cup B$
$\alpha + \beta = 1$.

Fig. 5.9. Three modes of political participation (or regime).

difference between the objective and the subjective conditions for a revolution. Let us take a quick look at two key concepts in political psychology: those of adhesiveness, and feeling of unfairness.

Whether or not a society is highly cohesive is of less consequence to its "survival" than the way that cohesiveness is "perceived". A social fabric with a low actual cohesiveness may be "seen" as highly cohesive (because e.g. of the repression of dissent); and conversely a highly cohesive society may be "seen" not to be so (because e.g. of a vocal nonconformist minority). The key concept here is that of attachment of an individual to a group or system. We may say that an individual feels attached to a social group or a social system if he believes that the benefits (material, cultural, emotional, etc.) he derives from sticking to it are greater than the price he has to pay for doing so. In other words, the *adherence* or *attachment* of individual x to a given group or system G_i is $A_i(x) = B_i(x) - C_i(x)$, where B and C are the benefit and cost functions respectively. There is positive attachment to G_i if the benefits outweigh the costs (i.e. $A_i(x) > 0$). Otherwise there is either rejection ($A_i(x) < 0$) by x of G_i or indifference ($A_i(x) = 0$) of x to G_i. The *total adherence* or *attachment* of individual x to a society σ formed by n social groups G_i is

$$A(x) = \sum_{i=1}^{n} A_i(x),$$

and the total *adherence* or *attachment of the membership* of σ to σ is

$$A(\sigma) = \sum_{x \in \mathscr{C}(\sigma)} A(x).$$

By choosing a suitable normalization factor, $A(\sigma)$ may be made to range, say, between -1 and 1. For example, the 1978 elections showed that the total adherence of the French people to their society is 0 (or $\frac{1}{2}$ on a [0, 1] scale).

Because adherence is psychosocial it can change swiftly in the light of information, misinformation, and criticism. When such means fail to enhance adherence, some structural social change is impending. Those in power can meet a decrease in popular attachment in either of two ways: with concessions or with coercion. The extent of either depends upon the imbalance between the actual adhesion value and the minimum value required for the social structure to remain unaltered.

Our second concept of interest is that of equity "perception". The political behavior of any political agent is partly determined by his "perception" of the equity or inequity of his station in society and his evaluation of the equity (or inequity) ideal. The imbalance between the two will contribute to his attachment or disaffection to the prevailing social structure. Therefore the social scientist is interested not only in actual equity but also in perceived equity, desired equity, and desirable or feasible equity. Let us take a quick look at these concepts.

Anything that can be distributed or allocated, from goods and services to leisure hours to political participation, can be assigned with various degrees of fairness or equity. Now, what is fair in one society may be unfair in another. Thus whereas in certain societies an average of 10 schooling years would be fair for all, in others this would constitute too heavy a burden, hence be unfair to the majority, and in still others it would be insufficient, hence just as unfair to the majority. This notion of an objectively desirable value of a property (such as the number of schooling years) must be distinguished from that of a subjectively desired value (desideratum). Whereas the latter may be unrealistic and incompatible with fairness, the former should in principle be determinable by studying the state of development and resources of the society. Such an objectively determinable value (or distribution, as the case may be) we shall call an *equity goal*, in contrast with the multiple *equity desiderata*.

We may assume that for each feature or variable there is one measure of equity or, dually, inequity. Whatever the feature may be, the objective inequity is some function f of the difference between the actual value X of the variable and its goal value G, i.e. $i(X) = f(X - G)$. *Example 1* The variable has a single value at a given time, as is the case with the mean number of schooling years. In this case a suitable inequity indicator is just the difference between G and X divided by the greater of the two. *Example 2* The feature in question is a distribution, such as that of arable land among the families of a society. If the goal is a straight line (e.g. the area of land is proportional to the number of families), then the Gini index is a suitable measure of inequity: see Figure 5.10. *Example 3* The goal distribution is symmetric – as is the case of the distribution of working hours *vs.* age. In this case inequity equals skewness, of which there are various measures.

The acuteness of the perception of inequity, as well as the desire for equity, depend on a number of factors in addition to actual inequity. One of them is social mobility. In a primitive society equity is taken for granted, whereas in a highly stratified society inequity may go just as un-

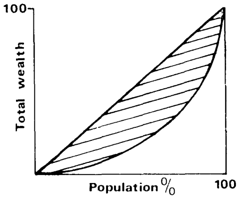


Fig. 5.10. Inequality in the distribution of wealth. The Gini index is the difference between the area under the straight line (equality) and the area under the actual curve.

questioned for being sanctified by ideology. On the other hand where social mobility is appreciable many persons feel status differences as iniquitous and also avoidable either by individual or group action. If the former proves ineffectual, the time is ripe for dissent and even sedition. We may then adopt the following version of the *Aristotle-de Tocqueville-Marx law*: Extreme inequity ends up by being perceived and negatively evaluated, that diminishes the attachment to the social structure, and this in turn leads to either indifference or active rebellion – in either case to a deterioration of the political system.

Needless to say, inequity may be economic, cultural, or political. Inequity felt in just one respect is neither necessary nor sufficient for a group to rebel against the social fabric. Any group that fits fairly well in the prevailing social (economic, cultural, and political) order – i.e. that is not marginal – is likely to be conservative even though that group may not be the principal beneficiary of that order. What do seem to be necessary and sufficient for members of a social group to rebel against the prevailing social order are (*a*) to feel being discriminated against in all three respects (economically, culturally, and politically), (*b*) to feel free from the traditions attached to the given social order (i.e. to be cultural not just economic or political outcasts), and (*c*) to be able to organize themselves into a system.

Finally we come to the notion of freedom. There are as many kinds of freedom as there are kinds of social behavior. Since human social activities occur in either of the three main artificial subsystems of society, we may group the species of freedom into three genera: economic, cultural, and political. Freedom to work (or to loaf) is economic freedom; freedom to learn is cultural freedom – and so is the freedom to remain ignorant; and freedom to participate in making decisions affecting the entire community is political freedom – and so is the freedom to remain politically inactive. Given the variety of freedoms and the fact that each has its opposite number, we should be wary of characterizing a society as free without further ado. We should specify in what respects and to what extent the members of a society are free or unfree. But such a specification presupposes an exact concept of freedom. Let us try and supply one, albeit one that is of interest to politology, namely that of *potestas agendi*, or freedom *to*, rather than that of freedom *from* (hunger, cold, fear, etc.). We may characterize the power to act by

DEFINITION 5.16 Let A be a set of alternatives, each consisting in engaging in an activity or in abstaining from it. Further, let x be an arbitrary member of a society σ. Then

(i) person x is *free* to do $y \in A$ in σ iff y is a possible choice for x & x can effectively do y & x values y & the benefit x expects to derive from doing y is greater than the cost to x of doing y;

(ii) society σ is *free in respect A* iff every member of σ is free to do any $y \in A$;

(iii) society σ is *free* iff σ is free in every respect, i.e. for any set A of alternatives (or choices).

Our definition of power or freedom to act rests on the notions of alternative or choice, of capacity or competence to perform an act, of value, and of cost and benefit – all of which are presumably elucidated in some discipline or other. It exhibits the dependence of freedom of action upon laws and circumstances: it construes freedom as depending on determinacy (whether causal, stochastic, or other) rather than on indeterminacy (hence lawlessness). In a lawless universe, in fact, there would be no freedom of any kind, since in order to be free do to something an agent must be able to count on certain regularities, at least those involving his possibilities, valuations, and actions.

We shall assume the rather platitudinous

POSTULATE 5.7 Every person and every society are free in some respects, none in all.

A completely free society – i.e. one in which every person were totally free – would be impossible, because the exercise of one person's freedoms is limited by that of his neighbors'. And a thoroughly enslaved society would be just as impossible, because every person needs to exercise some freedoms if only to survive and to contribute his or her share to society. Consequently neither extreme libertarianism nor extreme authoritarianism is a feasible blueprint for an enduring society – let alone an endearing one.

The matter of personal freedom constitutes the center of ideological debate in our time, yet it cannot be argued with profit on the ideological plane. On the other hand the systemic view of the political system can shed some light on that debate, namely as follows. A normal person is a component of some society or other. To survive, he or she must keep some measure of individuality or autonomy as well as engage in some synergic (harmonious) interactions with other components of the system, for otherwise the latter would break down. Indeed, exaggerating the autonomy of the individual would lead either to his or her breaking away from the system, or to subjecting the latter to the tyrannical control of the individual at the expense of the freedom of the other components. And overstressing the synergy of the whole may lead to depriving their components of creativity and thus to impoverishing society. So, if we care for both the system (not necessarily the "establishment") and the individual, we had better devise a political regime combining the good points of individualism with those of collectivism. But the matter of political regimes will have to be deferred to Vol. 7 of this *Treatise*.

4. SOCIAL STRUCTURE

4.1. *Root Social Relations*

We have drawn a distinction between a relation in general and a connection (or link, coupling or bond) in particular (Ch. 1, Sec. 1.2). In the case of social relations we distinguish social bonds, such as exchange relations, from nonbonding social relations such as that of belonging to the same occupational group. If a bond holds between two individuals, then at least one of them will behave differently from the way he or she would behave if not so bonded. On the other hand a nonbonding relation makes no difference to the relata. (Only the realization of belonging to the same social group may induce a feeling of either solidarity or hostility and thus influence social behavior. In the jargon of sociologists, the "perception" of a relation is bound to affect behavior.)

Among all the social bonds we now single out the root or basic ones, i.e.

those on which all the others depend – such as the kinship relations and the relations of economic, cultural, and political power. We may characterize them as follows:

DEFINITION 5.17 A *root* (or *basic*) social relation is a social relation that is
(i) bonding,
(ii) person to person (rather than system to system), and
(iii) an interaction (rather than a one-sided action).

We assume that all social relations are either basic or generated by relations of this kind:

POSTULATE 5.8 If σ is a society, then

(i) for any nonbonding person-to-person relation X in the structure of σ, there is a bonding person-to-person relation Y, in the same structure, such that, for any components a and b of σ, if Xab then there are components c and d of σ such that Ycd, where c and d are possibly equal to a and b respectively;

(ii) for any (bonding or nonbonding) system-to-system relation U in the family of subsystems of σ, there is a bonding person-to-person relation V in the structure of σ such that, for any subsystems x and y of σ, if Uxy, then there is at least one component a of x, and another b of y, such that Vab.

Example 1 Slave owners a and b, living in different places and times (hence not bonded), are socially equivalent ($\sim$) by virtue of being masters (M) of slaves (S): $a \sim b =_{df} (\exists x)(\exists y)(Sx \,\&\, Sy \,\&\, Max \,\&\, Mby)$. *Example 2* Factory a supplies concern b with merchandise (or goods) c, or $Sabc$ for short. This boils down to the following: members of a produce c, and members of a (the same or different) deliver c to members of b. In obvious symbols: $Sabc =_{df} (\exists x)(\exists y)(\exists z)(x \in \mathscr{C}(a) \,\&\, y \in \mathscr{C}(a) \,\&\, z \in \mathscr{C}(b) \,\&\, Pxc \,\&\, Dycz)$.

Social bonds may in turn be classed into voluntary and involuntary. Voluntary relations are those the individual can enter by choice – e.g. friendship, participation in community activities, and even – in industrial societies in times of full employment – job relations. Examples of involuntary social ties are the filial relation, the relation of being trained at a nursery school, the prisoner–captor relation, and the bondages of slavery and serfdom. We assume that, just as bonds determine nonbonding relations, so involuntary ties determine some of the voluntary ones. For example, being a prisoner, a serf, or a slave, determines most of the other relations a person can bear to other individuals. The mere existence and the basic character of involuntary relations suffices to brush aside the philosophy of voluntarism, according to which the individual will is the source of all behavior. The truth lies between the extremes of voluntarism and total determinism: man can act of his own free will (Theorem 4.3) but not always (Postulate 5.7).

Of all the involuntary social bonds family relations are the most basic because they are determined by reproduction, which is a biofunction. The family is thus situated at the biosocial interface. The root of the family is then the division of the sexes. In other words, the same-sex relation $\sim_s$ splits the total membership $\mathscr{C}(\sigma)$ of a society σ into two disjoint sets: males (M) and females (F). In short, $\mathscr{C}(\sigma)/\sim_s = \{M, F\}$. A human family of the nuclear or restricted kind may be defined as an aggregate of human coresidents among whom the relations of mate (or spouse) or of parenthood obtain. The relation μ of mate (or rather its graph) is included in the cartesian product $M \times F$. The relation π of being parent of somebody is a binary relation in $\mathscr{C}(\sigma)$. And the relation ρ of coresidence too may be construed as a binary relation in the same set. This is all we need to form

DEFINITION 5.18 Let σ be a society with sexual division $\mathscr{C}(\sigma)/\sim_s$, mate relationship μ, parenthood bond π, and coresidence tie ρ. The *nuclear family* $F(b)$ of the component b of σ is the sociosystem constituted by the mate(s) and the children of b who live with b:

$$\mathscr{C}(F(b)) = \{x \in \mathscr{C}(\sigma) \mid (\mu xb \vee \pi bx) \,\&\, \rho xb\},$$
$$\mathscr{E}(F(b)) \supset \mathscr{E}(\sigma) \,\&\, \mathscr{E}(F(b)) \cap \mathscr{C}(\sigma) \neq \varnothing,$$
$$\mathscr{S}(F(b)) = S \cup T, \quad \text{with } S = \{\mu, \pi, \rho\}.$$

A member of a nuclear family may have more than one spouse (as in the cases of bands, polygamy, and polyandry) provided all his or her mates are coresident. But each person belongs to exactly one nuclear family. (A childless widow constitutes a one person nuclear family but may belong to an extended family.) The set of nuclear families of a society is the composition of the nuclear kinship system of the society. That set is split into disjoint sets by the relation of belonging to the same family. The importance of this relation and of the partition it induces justifies making

DEFINITION 5.19 Let σ be a society. Then

(i) two components of σ are *family-wise equivalent* ($\sim_f$) iff they are components of the same family:

For any $x, y \in \mathscr{C}(\sigma)$, $x \sim_f y =_{df} (\exists z)\ (z \in \mathscr{C}(\sigma)\ \&\ x \in \mathscr{C}(F(z))\ \&\ y \in \mathscr{C}(F(z))\}$;

(ii) the *nuclear kinship system* of σ is the subsystem whose members are in some family or other, so that its membership is

$$\mathscr{C}_n(\sigma) = \{x \in \mathscr{C}(\sigma) \mid (\exists y)\ (y \in \mathscr{C}(\sigma)\ \&\ x \in \mathscr{C}(F(y))\};$$

(iii) the *family structure* of σ is the set of all the nuclear families of σ, i.e. the partition of $\mathscr{C}_n(\sigma)$ by the relation $\sim_f$ of family equivalence:

$$\mathscr{F}(\sigma) = \mathscr{C}_n(\sigma)/\sim_f.$$

Because of the biological root of the family, the family structure of a society constitutes its fundamental structure. So it is the basis of other social partitions. For example, a social class is a certain set of families, hence a subset of the family structure rather than a collection of individuals. So much for the so-called blood relations.

Other important social relations are those said to be "based on" work, i.e. those people enter by virtue of their work. Such are the "vertical" relations between a blue collar worker and a member of the management of his enterprise, and the "horizontal" relation between two workers on the same echelon in an organization. See Figure 5.11.

DEFINITION 5.20 Two persons hold a *bonding relation of production* iff either

(i) both individuals take part in the production of a set of products (goods or services) either as primary (L) or as secondary (K) workers; or

(ii) one of the individuals produces material or cultural goods while the other manages (controls, oversees) him or her; or

(iii) the two individuals comanage at least one producer.

In other words, the relations of production can be of coproduction, management, or comanagement. They are all, whether directly or indirectly, "based" on primary work insofar as, without the latter, there would be no

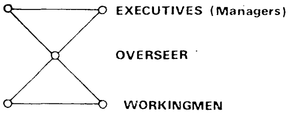

Fig. 5.11. Fragment of a particular web of social relations of production in an economic system.

production at all. And without the relations of production the social structure would be far poorer. Note, however, that not every relation of production is bonding. For example, the relation of belonging to the same occupational group, i.e. of doing work of the same type, is not bonding. It is only when individuals with the same occupation gather to form a guild, trade union, or some other organization "based on" work, that they enter into bonding relations. But these relations are no longer economic: they are political in our sense of the word, for their main impact is on social behavior rather than or production.

Whether economic, cultural, or political, social relations influence behavior. If such influence is decisive, we call it 'power' or 'control'. The social influences of all kinds fall under

DEFINITION 5.21 Let σ be a society where an activity of type $A \subset \mathscr{S}(\sigma)$ is performed. Then for any components x and y of σ, *x influences y in respect A* iff the activity of kind A performed by y while it communicates with x differs from that performed by y when it does not.

This definition makes room for indirect influences, i.e. those mediated by third persons. Thus even if a worker never sees a stockholder of his company, the two influence each other via the company management. (However, the influence relation we have just defined is not transitive – nor is it intransitive.)

Concerted influence is group pressure: this is not a mysterious influence exerted by a group as a totality, but the simultaneous and convergent influence of several individuals of group on a single individual. More precisely, we make

DEFINITION 5.22 Let $s \subset \mathscr{C}(\sigma)$ be a subset of the membership of a society σ. Then s exerts (group) *pressure* on a component x of σ in respect A iff each member of s influences x in respect A.

Power or *control* may be said to exist when influence is far stronger in one direction than in the opposite direction. It is possible to quantitate influence and power, hence to define a relation of power equivalence inducing the partition of the membership of a society into groups wielding the same power in some respect (Bunge, 1974d). However, we must rush on to other matters. The point of bringing in the above considerations is that, in order to disclose the social groups in a society, we must spot bonding social relations with the help of which (nonbonding) social equivalence relations can be defined, that induce the splitting of the membership of a society into homogeneous social groups. This is the method that we shall use to display the structure of a society.

4.2. *Social Structure*

Each social bond $B_k \in \mathbb{B} \subset S$ in a society generates a social equivalence relation $\sim_k$, which in turn induces a partition $\mathscr{P}_k = \mathscr{C}(\sigma)/\sim_k$ of the membership of the society σ into a family of homogeneous sets (social groups). There are as many such partitions as social equivalence relations. The collection of all such partitions we call the social structure of the society. More precisely, we propose

DEFINTION 5.23 Let σ be a society with composition $\mathscr{C}(\sigma)$ and call

$$\sim\; = \{\sim_k \mid \sim_k \subset \mathscr{C}(\sigma) \times \mathscr{C}(\sigma) \;\&\; \sim_k \text{ is an equivalence relation } \&\; 1 \leq k \leq n\}$$

the set of social equivalence relations definable on $\mathscr{C}(\sigma)$ on the basis of social bonds. Then

(i) the kth *primary social structure* of σ is the kth partition of $\mathscr{C}(\sigma)$, i.e. $\mathscr{P}_k(\sigma) = \mathscr{C}(\sigma)/\sim_k$, with $\sim_k \in \sim$;

(ii) the ith *social* group of the kth primary structure of (or *ik cell* of σ for short) is the ith member S_{ik} of

$$\mathscr{P}_k(\sigma) = \{S_{1k}, S_{2k}, \ldots, S_{ik}, \ldots, S_{mk}\}, \quad \text{with} \quad \bigcup_i S_{ik} = \mathscr{C}(\sigma) \text{ and } \bigcap_i S_{ik} = \varnothing;$$

(iii) the *overall primary social structure of* σ is the family of all the partial social structures of σ, i.e.

$$\mathscr{P}(\sigma) = \{\mathscr{P}_k \mid \mathscr{P}_k = \mathscr{C}(\sigma)/\sim_k \;\&\; \sim_k \in \sim \;\&\; 1 \leq k \leq n\}.$$

The overall social structure of a society is displayed by the matrix $\|S_{ik}\|$, every entry of which represents a social group or cell. (For the mathematics of set matrices see Bunge, (1974d).) The corresponding quantitative concept is got by just counting the population of each cell at a given time, i.e. by finding out how the total population $|\mathscr{C}(\sigma)| = N$ of the society is distributed among its various groups. Calling $N_{ik} = |S_{ik}|$ the population of cell S_{ik}, we can form the *population density matrix of* σ:

$$\|D_{ik}\| = (1/N)\,\|N_{ik}\|, \quad \text{with} \quad \Sigma_i N_{ik} = N.$$

A primary social structure is a partition of the membership of a society into groups or cells of individuals. But in some cases the groups themselves may band together to form larger groups or even systems. For example, the collection of families may be split into social classes, educational groups, income groups, political factions, and so on. Again, the collection of enterprises may be split into agricultural, industrial, and service enterprises – or into state owned, cooperative, and privately owned, and so on. Any such further partition of a primary partition will be called a secondary structure:

DEFINITION 5.24 Let $\mathscr{P}_k(\sigma) = \mathscr{C}(\sigma) / \sim_k$, with $\sim_k \in \sim$, be a primary social structure of a society σ. Then

(i) the *kmth secondary structure* of σ is

$$\mathscr{P}_{km}(\sigma) = (\mathscr{C}(\sigma) / \sim_k) / \sim_m, \quad \text{with} \quad \sim_m \in \sim \quad \text{and} \quad m \neq k;$$

(ii) the *overall secondary social structure* of σ is the totality of partial secondary structures of σ:

$$\mathscr{P}\mathscr{P}(\sigma) = \{\mathscr{P}_{km}(\sigma) \mid \mathscr{P}_{km}(\sigma) = (\mathscr{C}(\sigma) / \sim_k) / \sim_m \,\&\, \sim_m \in \sim \,\&\, m \neq k \,\&\, 1 \leq k, m \leq n\}.$$

Obviously not all such partitions are sociologically significant. For example, it makes no sense to group enterprises according to cultural background, or to partition the set of families into privately managed, cooperatively managed, and state managed. The sets resulting from such unnatural or insignificant partitions are either disregarded or set equal to the empty set. In particular, $\mathscr{P}_{kk}(\sigma) = \varnothing$. And, as with the case of the primary social structure, we can count items and build the density matrix of the overall secondary structure of a society.

Because both the primary and the secondary structures of a society are sets of sets, it might be wondered whether they stand for properties of the society. They do, for they may be regarded as values of property-representing functions, namely

$$\mathscr{P}_k \colon \Sigma \longrightarrow \{\mathscr{C}(\sigma) / \sim_k \mid \sigma \in \Sigma\} \quad \text{and}$$
$$\mathscr{P}_{km} \colon \Sigma \longrightarrow \{(\mathscr{C}(\sigma) / \sim_k) / \sim_m \mid \sigma \in \Sigma\},$$

where $\mathscr{C}(\sigma)$ is the membership of σ and Σ the totality of social systems. Furthermore, far from being arbitrary these functions occur in societal laws.

The concepts of overall primary and secondary social structures allow us to exactify the vague notion of social fabric: The *social fabric* of a society σ is the set of all primary and secondary social structures of σ, i.e.

$$\mathscr{P}(\sigma) \cup \mathscr{P}\mathscr{P}(\sigma).$$

Finally, one word about social class and class structure. Not all social groups are social classes, and therefore not all societies partitioned into groups need be stratified. A social class or caste is in a control relation with some other groups in the society. The control can be economic, political, military, administrative, or cultural. Such dominant groups originate in a variety of manners, from military conquest to gradual concentration of power. A typical case is that of medieval aristocracies. Small bands of soldiers, initially hired to defend a territory from marauders or from war lords, ended up by using military force to gain full economic and political control. What had been a horizontal division of society became a vertical one, i.e. a stratification or hierarchical order of social classes. This mechanism is quite general: the concentration of power in a social group turns it into a class. And, because power can be economic, cultural, or political, we need to distinguish three kinds of social class. That is, one and the same society may be divided into economic, cultural, and political classes. Occasionally these three partitions coincide, but in general they do not. For example, in a theocracy there are essentially two classes: the priestly caste, which wields total economic, political and economic power, and the laity. On the other hand in a contemporary Western democracy there are essentially two economic classes (the owners and the non-owners of the means of production), two cultural classes (the producers and the consumers of cultural goods and services), and – at least in theory – a single political class (the citizenry). We compress all this into

DEFINITION 5.25 Let σ be a society, and s and t two groups of σ. Further, let $\sim_A$ be a relation of social equivalence in respect A, where A stands for 'economy', 'culture', or 'polity'. Then

(i) group s *controls* group t in respect A iff every member of t is controlled in the respect A by some member(s) of s;

(ii) an *A-social class* is a social group that A-controls, or is A-controlled by, other social group(s) in the same society;

(iii) the *A-class structure* of σ is the partition of the composition of σ by $\sim_A$, i.e.

$$C_A(\sigma) = \mathscr{P}_A(\sigma) = \mathscr{C}(\sigma)/\sim_A;$$

(iv) the *class structure* of σ is the family of all partial class structures of σ, i.e.

$$C(\sigma) = \{\mathscr{P}_A(\sigma) \mid A = \text{economy, culture, or polity}\}.$$

If the quotient of $\mathscr{C}(\sigma)$ by $\sim_A$ fails to partition the composition of σ into disjoint subsets, then there is no A-control in the society, and thus the society is A-classless. In other words, σ is *classless* in the respect A iff $\mathscr{C}(\sigma)/\sim_A = \{\mathscr{C}(\sigma)\}$. It follows that an A-classless society is possible only if each of its components participates extensively in activities of kind A. The problem of participation will be addressed in the next subsection.

4.3. *Differentiation and Cohesion*

No society is homogeneous in all respects: every society is differentiated, i.e. split into social groups – if only sex and age groups. A natural though admittedly coarse measure of the difference between two social groups A and B is the numerosity of their symmetric difference $A \triangle B = (A \cap \bar{B}) \cup (\bar{A} \cap B)$. Hence we obtain a measure of the social differentiation (or variety) of a society by adding up the cardinalities of the pairwise differences among all its social cells, i.e. the $|S_{pq} \triangle S_{rs}|$. And, since it is convenient to have the resulting number comprised between zero and one, we divide the total by a suitable normalization factor. The end result (Bunge and García-Sucre, 1976) is

DEFINITION 5.26 Let σ be a society with social structure matrix $\|S_{ik}\|$, where $S_{ik} \in \mathscr{C}(\sigma)/\sim_k$ is the ith cell ensuing from the partition of $\mathscr{C}(\sigma)$ by the social equivalence relation $\sim_k \in \sim$. Further, let N be the total population of σ at a given time, and n the number of social equivalence relations (i.e. $N = |\mathscr{C}(\sigma)|$, $n = |\sim|$). Then the *degree of social differentiation* of σ with respect to $\sim$ at the given time equals

$$\delta(\sigma, \sim) = [2N(N-1)n^2]^{-1} \sum_{\sim_q \in \sim} \; \sum_{S_{pq} \in \mathscr{C}(\sigma)/\sim_q} \; \sum_{\sim_s \in \sim} \; \sum_{S_{rs} \in \mathscr{C}(\sigma)/\sim_s} | S_{pq} \triangle S_{rs}|.$$

This formula simplifies to

$$\delta(\sigma, \sim) = [n(N-1)]^{-1} \sum_k (n_k - 1),$$

where n_k is the number of cells produced by the kth partition, i.e. $n_k = |\mathscr{C}(\sigma)/\sim_k|$.

Minimal differentiation occurs when each partition produces a single class, namely $\mathscr{C}(\sigma)$ itself – i.e. when everyone is everything. In this case $\delta = 0$. At the other end of the spectrum there is just one individual in each social group, i.e. $|S_{ik}| = 1$ and $n_k = N$ for each pair (i, k). The corresponding value is $\delta = 1$. We take it that neither of these extreme values is realistic. The intermediate case is that in which all cells are uniformly populated, i.e. $|S_{ik}| = m$ and $n_k = N/m$, with $1 < m < N$ for every k. The corresponding degree of differentiation is

$$\delta(\sigma, \sim) = (N - m)/m(N - 1) \longrightarrow 1/m \quad \text{for } N \longrightarrow \infty.$$

A person who belongs to a social group is said to *participate* in it. Participation calls for differentiation: there is no occasion to participate if there are no different social groups. (However, participation is also nil if differentiation is maximal, since in the latter case no individual belongs to more than a single social group.) The individual participations aggregate to form a systemic property that may be called the *overall participation* in a society. This is made up of the overlaps of all the social groups, i.e. of $S_{pq} \cap S_{rs}$. More precisely, we make

DEFINITION 5.27 Let σ be a society whose composition is partitioned by the n equivalence relations contained in $\sim$. Then

(i) the *degree of participation of group* S_{pq} in σ is

$$\pi(S_{pq}, \sigma, \sim) = \sum_{\sim_s \in \sim} \sum_{S_{rs} \in \mathscr{C}(\sigma)/\sim_s} |S_{pq} \cap S_{rs}| \, / \, |S_{rs}|;$$

(ii) the *degree of marginality* (or *alienation*) of group S_{pq} in σ is the complement to unity of its degree of participation, i.e.

$$\mu(S_{pq}, \sigma, \sim) = 1 - \pi(S_{pq}, \sigma, \sim);$$

(iii) the degree of *overall participation* in σ is

$$\pi(\sigma, \sim) = F \sum_{\sim_q \in \sim} \sum_{S_{pq} \in \mathscr{C}(\sigma)/\sim_q} \sum_{\sim_s \in \sim} \sum_{S_{rs} \in \mathscr{C}(\sigma)/\sim_s} |S_{pq} \cap S_{rs}|,$$

where F is the normalization factor ensuring that the maximal value of π is 1;

(iv) the degree of *overall margination* (or *alienation*) in σ is

$$\mu(\sigma, \sim) = 1 - \pi(\sigma, \sim).$$

From the findings of social scientists we infer that all societies are differentiated, though none maximally, and that there is some measure of participation in all. That is, we propose

POSTULATE 5.9 For every society σ, $|\sim| > 1$, and $0 < \delta(\sigma, \sim) < 1$, $0 < \pi(\sigma, \sim) < 1$.

Every society is more or less cohesive: were it not, it would not be a system. Social cohesion is of course one of the emergent societal properties: it is a systemic property not possessed by any of the individuals composing a society. Cohesion can be spontaneous, forced, or a combination of the two. Spontaneous cohesion, the one that does not result from coercion, is undoubtedly the more important of the three. When strong it ensures the stability of the social fabric; when weak it calls for either structural change or the violent repression of any attempt to effect structural changes.

In Ch. 4 we assumed that cohesion derives from sharing (of things and services) and participation (in activities): recall Postulate 4.24. We shall presently discuss a measure of spontaneous cohesion based on that assumption (Bunge and García-Sucre, 1976). No participation at all, i.e. extreme segregation, results in instability, which ends up in fragmentation. Yet maximal participation has a similar dissolving effect, for a society of equals in every respect is a collection of competitors in no need of mutual assistance, i.e. in no need of belonging to the society. In other words, if every individual is either nothing or everything in a society, i.e. utterly marginal or ubiquitous, then cohesion is minimal. Maximal cohesion must then occur somewhere in between, when each individual shares several, though by no means all, cells with fellow members. In sum, cohesion must result from moderate participation. We proceed to formalize this intuitive idea.

The more members two social groups share the stronger they are bonded. However, these bonds operate only if the groups are different, in particular functionally complementary to one another. More precisely, the effective bonding between two social groups A and B is the numerosity of their intersection times that of their symmetric difference, i.e. $|A \cap B| \cdot |A \triangle B|$. A low degree of differentiation (i.e. a small $|A \triangle B|$ value) may be compensated for by a high degree of participation (i.e. a large overlap value $|A \cap B|$) and conversely. Certainly differentiation by itself does not contribute to cohesion, but the various partitions (structures) may intertwine in such a manner that cohesion results: i.e. cells situated in different columns of the social structure matrix may overlap partially. By adding up all the pairwise bonds among the social groups of a society we obtain its cohesion:

DEFINITION 5.28 Let σ be a society whose composition is partitioned by the n social equivalence relations contained in $\sim$. Then the degree of *spontaneous social cohesion* of σ with respect to $\sim$ equals

$$\kappa_s(\sigma, \sim) = [2N(N-1)n^2]^{-1} \sum_{\sim_q \in \sim} \sum_{S_{pq} \in \mathscr{C}(\sigma)/\sim_q} \sum_{\sim_s \in \sim} \sum_{S_{rs} \in \mathscr{C}(\sigma)/\sim_s} |S_{pq} \cap S_{rs}| \cdot |S_{pq} \triangle S_{rs}|,$$

where the *pqrs* term in the summation represents the strength of the bond between cells S_{pq} and S_{rs}, this strength being the product of the social participation by the differentiation.

Disjoint cells do not contribute to cohesion while overlapping cells do, provided they differ somewhat. If the nonempty overlaps all have unit measure, i.e. $|S_{pq} \cap S_{rs}| = 1$ for all pairs of cells except those along the same column of the social structure matrix, then cohesion reduces to differentiation (Definition 5.26). If on the other hand all the local differences are the same, and in particular $|S_{pq} \triangle S_{rs}| = 1$, then cohesion coincides with participation (Definition 5.27).

Minimal differentiation accompanies minimal cohesion. In fact, if $|S_{ik}| = N$ and $n_k = |\mathscr{C}(\sigma) / \sim_k| = 1$ for every k, then $S_{pq} = \mathscr{C}(\sigma)$ regardless of q, whence $S_{pq} \triangle S_{rs} = \varnothing$ in all cases, whence $\kappa_s(\sigma, \sim) = 0$. Likewise maximal differentiation ensues in a total lack of cohesion. Indeed, if $|S_{ik}| = 1$ and $n_k = |\mathscr{C}(\sigma) / \sim_k| = N$ for every k, the overlaps are nonvoid just in case the cells coincide, which implies that the symmetric difference is nil. In sum, in this case too $\kappa_s(\sigma, \sim) = 0$. Finally consider the intermediate case of homogeneity: $|S_{ik}| = m$ and $n_k = |\mathscr{C}(\sigma) / \sim_k| = N/m$ for every k, and $|S_{pq} \cap S_{rs}| = t$ unless the cells are in the same column. It turns out that in this case

$$\kappa_s(\sigma, \sim) = Nt(m-t)/(N-1)m^2 \cong t(m-t)/m^2.$$

The maximal value of spontaneous cohesion for this homogeneous case occurs for $t = m/2$ and is

$$\kappa_s(\sigma, \sim) = \tfrac{1}{4}N/(N-1) \cong \tfrac{1}{4}.$$

In short, the spontaneous cohesiveness of a society consists in a moderate participation of its members in the various social groups of the community. If the latter is hardly differentiated, there is not much to participate in, and competition overpowers cooperation, whence cohesiveness is low. And if the differentiation is rigid, as is the case with hierarchical societies (e.g. caste systems), there is not much participation either: in this case stability does not result from spontaneous cohesiveness but is imposed by force of arms or of ideology.

In contrast to spontaneous cohesion, forced cohesion is related to cultural or political repression, i.e. to the action of organized ideologies (e.g. churches and parties) or to police forces and the like. Though forced cohesiveness is an output variable, it can be roughly indicated by the corresponding input, namely the strength of the repressive forces relative to the total population. Calling $\kappa_f(\sigma)$ whatever indicator of the degree of forced cohesion we may choose, we can define the *total cohesiveness* of σ as $\kappa(\sigma) = \kappa_s(\sigma) + \kappa_f(\sigma)$. (In disregarding the set $\sim$ of social equivalence relations used to compute $\kappa_s(\sigma)$ we are tacitly assuming that all "significant" relations of that kind are being taken care of.) In principle, $\kappa(\sigma)$ is comprised between 0 and 2.

There are a number of definitions of the concept of a free society. Since most of them are ideological rather than scientific, there is little hope of achieving consensus. Thus while X will rightly count the freedom of the press among the necessary conditions for a free society, Y will counter, equally correctly, that such freedom is illusory as long as it can be exercised only by those with the economic freedom to run the press. We can avoid this debate by proposing an objective and even quantitative criterion of *political freedom*, namely this: A society is *politically free* iff its spontaneous cohesiveness is much greater than its forced cohesiveness.

If a society is not politically free, i.e. if its social structure is kept or modified by force of arms or ideology, then this force overpowers, balances, or eventually elicits a rebellion on the part of some social groups. However, the strength of the disruptive forces in a society is not just proportional to its numbers. Indeed, a small band of enthusiastic and well organized revolutionaries espousing a popular cause, or else acting amidst popular indifference, may defeat a large army of demoralized supporters of an unpopular dictatorship, just as a large mass of disorganized rebels will be no match for a small but highly trained repressive force. Consequently the politologist, unlike the sociologist, must study not only the indicators of objective cohesiveness but also those of "perceived" cohesiveness, or adherence (Sec. 3.3).

4.4. *Social Relations and Structures: Real?*

While holists acknowledge the reality of social relations, they reduce them to two types: the whole–whole (or system to system) relations – exemplified by international relations – and the whole– part causal relation, allegedly exemplified by group pressure. They are interested more in mythical wholes hovering above individuals – such as the Nation, the State, and the Spirit of the Times – than in interpersonal relations. The latter are on the other hand stressed by individualists: "Repeated interactions between particular persons are the very guts and marrow of social life" (Homans, 1974, p. 57). The systemist gives full assent to this view but he also admits intersystem bonds (e.g., Postulate 5.8(ii)). And he insists that social bonds, whether interpersonal or intersystemic, are real as long as they accompany changes in the relata (individuals or sociosystems). Consequently social structures are perfectly real, and moreover the main concern of the sociologist.

Social scientists rarely espouse the extremes of holism and individualism: most of them study social systems and their subsystems. And, whether they sympathize with holism or with individualism, they rarely deny the reality of social relations and, as a consequence, the reality of social structures. (Structuralist anthropology is an exception: it claims that social structures are in the head of the anthropologist. See Lévi-Strauss, 1963. For a devastating criticism see Harris, 1968.)

On the other hand the philosophers of social science who favor ontological and methodological individualism tend to deny the reality of social bonds, hence of social structures, perhaps because of their eagerness to deny the reality of the wholes extolled by the holists. Thus Winch (1958, pp. 131 ff.) has claimed that *all* "social relations between men exist only in and through their ideas", and "fall into the same logical category as do relations between ideas", so that social science is a chapter of epistemology. And Popper (1974, p. 14) has stated that "social relations belong, in many ways, to what I have more recently called 'the third world', or 'world 3', the world of theories, of books, of ideas, of problems". We saw in Ch. 4, Sec. 4.5, that there is no such thing, because a genuine world – i.e. a system – cannot be composed of both concrete things, such as books, and fictions, such as ideas in themselves (i.e. apart from ideating brains). Here we shall note only how convenient it would be for all oppressors to be able to persuade their subjects that their bondage belongs in the world of fairy tales and mathematical formulas, so they could not possibly suffer from it, let alone rebel against it.

Sociologists, who study social relations and social structures, and politicians, who attempt to control them, cannot take seriously the claim that social bonds and the social organizations they constitute are fictions. They regard them as just as real as physical or chemical bonds. Hence, when intent on changing them they resort to social action rather than incantation.

5. SOCIAL CHANGE

5.1. *The Social Structure Approach*

A social change is a change in some of the social properties of a community, such as a change in cultural level, or a redistribution of economic or political power. In principle it is possible to account for social change with the help of the concept of state function: the instantaneous state of a society would be the value of its state function at the given time, and the history of the society over a certain period would be the list of all the instantaneous values of its state function. This approach to social change should work for small sociosystems. But even a rough determination of the overall economic, cultural and political state of a modern society would require a staggering amount of information. And an account of its evolution would require an equally staggering number of equations of evolution (which in the simplest case would be rate equations for the state functions). We shall therefore adopt a more feasible method.

We shall assume that every social change consists in the redistribution of the composition of a society among the various cells of the social matrix $\|S_{ik}\|$. (For example, the emergence or the disappearance of a given kind of work, or of a given power relation, will ensue in the formation or extinction of the corresponding social cells.) Hence tracing the evolution of a society boils down to taking a periodic census – which is of course what the census bureaus do. This procedure will give us a precise, albeit coarse, description, though not an explanation, of social change. More precisely, we can make

DEFINITION 5.29 Let σ be a society with social structure matrix $\|S_{ik}\|$ and corresponding population density matrix

$$D(\sigma, t) = (1/N(\sigma, t)) \cdot \|N_{ik}(\sigma, t)\|.$$

The *net structural change* in σ over the time interval $[t_1, t_2]$ is

$$\Delta(\sigma; t_1, t_2) = D(\sigma, t_2) - D(\sigma, t_1).$$

Example At t_1, σ is divided into two social classes: masters (M) and slaves (S). At time $t_2 > t_1$, σ is leveled to a society of free men (F) with conservation of the total population. (I.e. either the revolution has been bloodless or the losses in lives have been compensated for by births or immigration.) The net class change (or change in class structure) is then

$$(1/F) \cdot \begin{Vmatrix} 0 \\ 0 \\ F \end{Vmatrix} - (1/F) \cdot \begin{Vmatrix} M \\ S \\ O \end{Vmatrix} = (1/F) \cdot \begin{Vmatrix} -M \\ -S \\ F \end{Vmatrix}, \quad F = M + S.$$

A negative (positive) sign indicates population loss (gain) in a cell. It goes without saying that, by virtue of the interrelations among the various social properties, a full account of this (imaginary) social revolution would require an investigation of all the major social cells.

Whatever causes, natural or social, may influence the distribution of the total population of a society among its cells, may be lumped into a social evolution operator. We assume that this operator satisfies

POSTULATE 5.10 Let $D(\sigma, t_1)$ and $D(\sigma, t_2)$ represent the social structure of a society σ at times t_1 and t_2 respectively. Then there exists an operator $E(\sigma; t_1, t_2)$ such that

$$D(\sigma, t_2) = E(\sigma; t_1, t_2) D(\sigma, t_1)$$

representing the mode of change of σ over the period $[t_1, t_2]$ and called the *social evolution operator* for that period.

This is a substantive assumption that may be found empirically wanting, particularly over a long period: the actual social evolution may well be nonlinear for all we know. However, we may assume that the postulate holds at least for short periods.

From the above postulate and Definition 5.29 it follows that the net structural change is

$$\Delta(\sigma; t_2, t_1) = (E(\sigma; t_1, t_2) - I)\, D(\sigma, t_1),$$

where I is a suitable unit matrix. Given the initial state $D(\sigma, t_1)$ and the mode of evolution $E(\sigma; t_1, t_2)$, the final structure, i.e. $D(\sigma, t_2)$, remains uniquely determined. This is the direct or forecast problem. The inverse or explanation problem is this: Given the values of the density matrix at two different times, e.g. now and one decade ago, find the mode of evolution, i.e. compute the evolution operator. Being an inverse problem, in general it lacks a unique solution and is much harder than the forecast problem. In fact, consider again the example studied a moment ago. The following evolution operators, among others, account for the same structural change:

$$E = \begin{Vmatrix} -1 & 0 & 0 \\ 0 & -1 & 0 \\ 1 & 1 & 0 \end{Vmatrix} \quad \text{and} \quad E = \begin{Vmatrix} -1 & 0 & 1 \\ 0 & -1 & 1 \\ 1 & 1 & 1 \end{Vmatrix}.$$

It can be shown in general that the following holds (Bunge, 1974d):

THEOREM 5.1 Any given or prescribed social change in a society can be brought about in alternative ways, each represented by a different social evolution operator.

Further, since the populations along any given column of the social structure matrix must add up to the total population, we also have

THEOREM 5.2 The relative growth of any cell in a column of the social structure matrix occurs at the expense of the relative decay of some other cell(s) in the same column.

For example, if a column consists of just two cells and one of them grows exponentially, then the other must decay exponentially. Thus all growth has to be paid for by some decline.

Finally, note that social change is the likelier the more heterogeneous or varied a society is, and this if only because the more social cells there are, the more numerous the possible transitions among them. For the same reason, the more homogeneous a society the less changeable it is.

5.2. *History*

The main types of structural change of a society are listed in

DEFINITION 5.30 Let σ be a society with social matrix $\|S_{ik}\|$ and population matrix $\|N_{ik}\|$. Then

(i) σ remains *stationary* (or in a state of *static equilibrium*) in the kth respect (where $1 \leq k \leq n$) over the period $[0, \tau]$ iff $N_{ik}(t) =$ constant for all $1 \leq i \leq n$ and all $t \in [0, \tau]$;

(ii) σ is stable (or in a *state* of *dynamical equilibrium*) in the kth respect $(1 \leq k \leq n)$ over the period $[0, \tau]$ iff all the cells in the kth column of $\|S_{ik}\|$ expand or shrink at the same rate:

$$N_{ik}(t) = at \quad \text{with} \quad a \in \mathbb{R}^+ \quad \text{and} \quad a \neq 1 \quad \text{for all } 1 \leq i \leq m;$$

(iii) σ undergoes *cyclic changes* iff there is an evolution operator E and a natural number p such that $p = \tau$ and $E^p = I$;

(iv) σ undergoes an *irreversible* change iff σ changes in a noncyclic way;

(v) σ undergoes a *partial revolution* iff some cells S_{ik} change appreciably (in particular if they are either filled up or emptied);

(vi) σ undergoes a *total revolution* iff all the cells S_{ik} change appreciably.

Example A society consists initially of four social classes, 1, 2, 3, and 4, with populations N_1, N_2, N_3, and N_4 respectively. A revolution wipes out all but a fraction f_i of each class, and merges 1 with 2, and 3 with 4. A possible representation of the net change is this:

$$\begin{Vmatrix} f_1 & f_2 & 0 & 0 \\ 0 & 0 & 0 & 0 \\ 0 & 0 & f_3 & f_4 \\ 0 & 0 & 0 & 0 \end{Vmatrix} \begin{Vmatrix} N_1 \\ N_2 \\ N_3 \\ N_4 \end{Vmatrix} = \begin{Vmatrix} f_1N_1 + f_2N_2 \\ 0 \\ f_3N_3 + f_4N_4 \\ 0 \end{Vmatrix}$$

$$V = 1 - (1/N(0)) \textstyle\sum_i f_i N_i(0).$$

This index equals 0 for peaceful revolutions, $\frac{1}{10}$ for those that decimate each social stratum, and $\frac{1}{2}$ for those that take the lives of half the population in each group.

So far we have drawn no distinction between spontaneous and planned social change – hence between descriptive models and prescriptive ones. But all contemporary societies, even those with economic free enterprise, are subjected to planning to some degree or other, and it may be argued that they need more (and better) of the same if they are to survive. Take the rather obvious case of population growth. In the absence of any social or cultural constraints, and pretending that there are no environmental strictures either – in particular no interpopulational competition – the expected population size satisfies the rate law

$$\dot{N} = aN, \quad \text{with} \quad a = \text{birth rate} - \text{death rate}.$$

Here $a \in \mathbb{R}$ is a parameter summarizing biological, economic, cultural, and political characteristics, such as fertility, health level, food supply, and feeling of security. If $a > 0$, the population grows exponentially, if $a = 0$ it has zero growth, and if $a < 0$ it declines exponentially. Add now family planning on an individual basis, such as practised in all industrialized nations. Anything can happen depending on economic, cultural and political changes: the expected population size may increase, decrease, oscillate, remain stagnant, or neither.

Consider next family planning associated with the adoption of an explicit desideratum concerning the desirable family size. This norm will result in a total population goal G. A new law of population growth emerges, one that is controlled by the families themselves jointly with state organizations. In the simplest case this law takes the form

$$\dot{N} = b(G - N)\begin{cases} > 0 & \text{iff } N < G \text{ (underpopulation)} \\ = 0 & \text{iff } N = G \text{ (attained ideal)} \\ < 0 & \text{iff } N > G \text{ (overpopulation).} \end{cases}$$

Now population growth is under control. The total population grows exponentially (barring war, pestilence or famine) just in case the actual population is inferior to the goal value. It remains constant if the ideal has been attained. And it declines as soon as the goal is surpassed.

The above pattern of planned social change can obviously be generalized to an arbitrary social cell, such as a given occupational or educational group. As a matter of fact all modern nations do plan and control a number of activities, particularly agriculture and education: just think of the subsidies to the former and of the restrictions on entrance to medical schools.

Note the following points. First, mathematics can handle goals or norms; moreover, only with the help of mathematical models can social change be steered successfully. Second, knowledge and valuation can change the laws of social change. Such modifications consist, essentially, in the deliberate introduction of feedback terms of the form $G - X$, where X is the current value and G the corresponding goal value of a state variable. Third, controls are not restricted to temporal patterns but can be generalized to changes of all kinds. For example, if the spatial distribution of a social cell (e.g. farmers, craftsmen, or medical doctors) is to be controlled, the social planner will regard the density of each cell as a function of both spatial and temporal coordinates, and will set up diffusion equations containing feedback or control terms.

Whether spontaneous or planned, the social changes occurring in each social cell of a society form a time series or temporal sequence. And the whole bundle of such partial social histories, one per cell, constitutes the global social history of the given society. More precisely, we make

DEFINITION 5.31 Let σ be a society with instantaneous social structure (or density matrix) $D(\sigma, t)$. Then

(i) the *history* of the S_{ik} cell of σ throughout the period $[0, \tau]$ is the sequence

$$H_{ik}(\sigma; 0, \tau) = \langle D_{ik}(\sigma, t) \mid t \in [0, \tau] \rangle;$$

(ii) the *social* (or *anonymous*) *history* of σ over the period $[0, \tau]$ is the matrix $H = \|H_{ik}\|$ composed of all the social cell histories.

In other words, by collecting the values of the density of a cell over a period of time we obtain the history of that cell during that period. And doing the same for every cell in the social structure we come up with the social history of the society. (This may be dubbed the 'demographic view' of social history.) Obviously it will include the net effects of the contributions of the individual components of the society, though not their biographies. I.e. social history does not display the accomplishments of great men or great crooks: it is anonymous, therefore harder to reconstruct than biography. It attempts to describe, and eventually to explain, the evolution of entire cells, societies, and supersystems of such. It attacks big problems, in particular the coming into being and evolution of entire social cells, organizations, and institutions. For example, social history is concerned with the origin of agriculture and of capitalism, the origin of the state and of organized religion, the expansion of the world market and advanced technology.

A systemic approach to social history encourages studying the evolution of systems proper rather than artificial units such as many a kingdom resulting from war or political compromise. Such social systems may be circumscribed such as the Florentine banking system during the Renaissance, or vast like the Mediterranean basin during the same period (cf. Braudel, 1949). And, of course, a systemic approach will emphasize rather than ignore the interdependence among the various subsystems. For example it will study the evolution of the military–industrial complex, i.e. the symbiotic system composed of certain industries and the military. Or it will investigate the various facets of the Green Revolution, which started in the laboratory, changed the agrotechnics of India and elsewhere, and unexpectedly ended by worsening the lot of the poor peasants. So much for piecemeal social engineering, or the reform policy that ignores the interrelationships among the economic, the cultural, and the political subsystems of any society.

6. CONCLUDING REMARKS

We have sketched a systemic view of society, which may be regarded as a synthesis of two traditional conceptions: individualism (or atomism), and collectivism (or holism). In fact we regard society or any of its subsystems neither as an aggregate of individuals nor as a mystic totality hovering above its humble membership, but rather as a system composed of persons bonded by social relations. These ties generate social equivalence relations, such as those of belonging to the same economic, cultural, or political group. And these relations in turn partition the composition of a society, at a given time, into social cells or equivalence classes – such as the group of destitutes, or of illiterates, or of people deprived of political rights. Every such partition, or set of social cells, constitutes a social structure, or rather a primary social structure. A secondary social structure rides on the former, as when the set of families is classed into equivalent income groups. The totality of social structures of a society, both primary and secondary, constitutes its social fabric.

The systemic view of society should not be mistaken for the *organismic* view, a variant of holism according to which sociosystems are organisms. Surely the components of sociosystems are alive; besides, sociosystems are born, develop, and become extinct. However, they are not alive: if they were then all of the peculiar laws of the living, and in the first place those of genetics, would hold for them. But these do not, hence sociosystems are not alive. Nor are they dead: the categories of life and death do not apply to sociosystems. This is not to say that sociosystems are suprabiological, in particular spiritual entities, or that they are infrabiological, in particular chemical, systems. Sociosystems are concrete systems with peculiar properties and laws. They are concrete because they are composed of concrete things interacting in concrete ways and because they transform energy and effect changes in their environment. But they are as little physical or chemical systems as they are biosystems. This view of sociosystems may be christened *systemic materialism*, provided 'systemic' is not mistaken for 'holist' and 'materialism' is not construed in the narrow physicalist way.

We have introduced a method for both describing the structure of a society and keeping track of its multifarious changes, namely the social structure approach. The individualist is bound to dislike it because it achieves what he holds to be impossible, namely describing the state, and the changes of state, of a society as a whole. But he cannot in good faith dismiss it as being "merely a holistic confusion", for it is based on a conception of society which, being systemic, is neither holist nor individualist. Besides, the method is mathematically transparent, so it cannot be branded as confused – in particular because it does not involve the individualistic confusion of a sociosystem with its composition.

Our structural approach to social change ensues in a view of social (or anonymous) history which is as precise as it is shallow: it only recounts how the social cells are populated or depleted. But at least this view of social history is superior to both the great hero myth and the great whole myth. It is moreover consistent with contemporary social history and social demography. And far from ignoring the individual it encompasses every individual contribution with a social impact – i.e. that influences the social behavior of other individuals. Finally, nothing prevents the social scientist from supplementing our descriptive account of social structure and social change with mechanismic models capable of explaining the current structure and its development.

Besides a general framework for the study of social systems, we have introduced definite measures of certain emergent social properties, such as social differentiation, participation, and cohesion. And we have submitted that every society, however primitive, is made up of four main subsystems: the kinship, economic, cultural, and political ones. These are not independent spheres but interdependent subsystems. Therefore the neglect or ill health of any of them will sooner or later lead to a deterioration of the others. And, because of the feedback links among the various subsystems, favoring either at the expense of the others will eventually result in a decay of the very favored subsystem.

Thus *economism* ensues in the wilting of culture, which may include a technology indispensable to keeping the economy up to date; and it will tend to leave politics in the hands of "those who know best", thus fostering a concentration of power that will eventually stifle both the economy and the culture. Likewise *politicism*, or the exaggeration of the role of politics, may lead to a disruption of the very economy and culture that politics is supposed to serve, to the point that not much worth being managed may remain. Analogously *culturalism* would end up by draining the economy and drying up the political life, which would backfire on culture itself by depriving it of sustenance and political influence. All this, which is obvious from our systemic point of view, entails a moral that has yet to be learned by most political, economic, and cultural leaders, to wit: In a healthy society there is a balance among its main subsystems, even during periods of vigorous growth. In particular, there is no unilateral (e.g. exclusively economic) development – nor is development the same as growth.

Although we have proposed a handful of substantive hypotheses on the nature of sociosystems, ours is mainly a framework for the study of things of that kind, in particular for the building of theories in social science. (See Bunge (1974d) for the difference between framework and theory.) And surely no framework, however suggestive, is a substitute for a full fledged testable theory. Yet while some frameworks block, others facilitate the conception of theories. Ours discharges its heuristic function in the following ways:

(i) It invites studying social systems rather than either outstanding individuals or amorphous sets of persons or totalities way above individuals. In this way it stimulates the search for societal properties and laws.

(ii) It directs one to identifying the coordinates of every social system – its composition, environment (natural and artificial), and structure. In this way neither the people nor the environment nor the social reslationships can be lost sight of.

(iii) It stimulates the analysis of extremely large and complex systems into more manageable subsystems with their own inner dynamics as well as their mutual actions. Without such analyses hardly any scientific study of society is possible.

(iv) It suggests spotting and characterizing the three chief artificial subsystems of every society – the economy, the culture, and the polity. Thus it helps avoiding the pitfalls of economism, culturalism, and politicism.

(v) It guides the search for relationships among the components of each subsystem as well as among the subsystems of every system. Hence it avoids the fallacies of the lone wolf and the isolated organization.

(vi) It clarifies and simplifies the study of the so-called cross relations, or relations among relations, by constructing them as links among system components or subsystems – with considerable gain in clarity and economy.

(vii) It makes room for cultural, in particular ideological, influences in every walk of social life. But it avoids the reification of cultural activities and is itself ideology-free.

(viii) Although it is ideology-free, our framework does suggest certain social policies, such as that of combining equity with participation in the interests of social cohesion and therefore stability.

This concludes our study of sociosystems and at the same time that of all other genera of concrete system. We return now to the general concept of a concrete system, with the advantage of our realization of the diversity of kinds of system, hence of change.

CHAPTER 6

A SYSTEMIC WORLD VIEW

In this, the last chapter, we shall generalize some of the results of the previous chapters. We shall thus come up with the core of a systemic world view. This *Weltanschauung* is a continuation of certain philosophical traditions and is also in tune with contemporary science. But it should not be mistaken for the popular "systems philosophy," a new version of holism according to which every thing is a system (false) and the patterns of being and becoming are basically the same at all levels (false). Our systemist philosophy is neither holistic nor atomistic: it acknowledges the variety of properties, kinds and patterns found in the world and, by using certain elementary formal tools, it avoids the obscurities of traditional philosophy. Ours is, in short, a kind of scientific ontology. (Cf. Vol. 3, Introduction.) Let us review some of its assumptions.

6.1. *A World of Systems*

An assumption of this book and its companion, *The Furniture of the World* (Vol. 3), is that there are no stray things: that every thing interacts with other things, so that all things cohere forming systems. That is, we propose

POSTULATE 6.1 Every concrete thing is either a system or a component of one.

Another assumption is that systems come in Chinese boxes or nested systems. Hence, given any system but the world, one may expect to find that it is part of some supersystem. (The converse is false: not every system component is itself a system. There seem to be basic or simple things, such as electrons and photons.) Thus we lay down

POSTULATE 6.2 Every system except the universe is a subsystem of some other system.

Finally, the universe itself is neither a mere thing nor a loose aggregate of things but a system of systems:

POSTULATE 6.3 The universe is a system – namely the system such that every other thing is a component of it.

From the previous assumptions, together with some of our axioms on things and change (Vol. 3), a number of further sweeping generalizations follow. One such theorem is that every system is engaged in some process or other. Second: Every change in any system in lawful. Third: Because every subsystem acts upon or is acted on by other subsystems, it exists somehow *per aliud* (by another) rather than autonomously. Fourth: The universe as a whole exists *per se* (by itself) – and moreover it is the only absolute (autonomous) existent. Fifth: The universe has neither beginning nor end in time: it endures eternally although no part of its does.

6.2. *System Genera*

Philosophers are not equipped to ascertain what kinds of system there are or could be in the world: they can only take note of the variety of systems that science discovers, and help categorize them. Current science, pure and applied, seems to accept the existence of five system genera. (Recall that a kind, such as a species or a genus, is said to exist just in case it is not empty. Strictly speaking only the members of a kind can be said to exist really. Cf. Vol. 3, Ch. 3, Sec. 4.3.) The system genera characterized in the previous chapters are:

S_1 = *Physical*
Microphysical, e.g. atoms and small scale fields
Mesophysical, e.g. bodies and large scale fields
Megaphysical, e.g. galaxies
S_2 = *Chemical*
Microchemical e.g. chemical reactors involving only monomers
Mesochemical, e.g. chemical reactors involving polymers
Megachemical, e.g. compost piles
S_3 = *Biological*
Microbiological, e.g. single cells
Mesobiological, e.g. individual multicellular organisms
Megabiological, e.g. ecosystems
S_4 = *Social*
Microsocial, e.g. families
Mesosocial, e.g. villages and concerns
Megasocial, e.g. large cities and nations
S_5 = *Technical*
Microtechnical, e.g. this book

Mesotechnical, e.g. farms and industrial plants

Megatechnical, e.g. a lumber-paper manufacturing-and-commercialization system.

Remark 1 We have not lumped physical and chemical systems into a single category for the following reasons. Firstly, not all physical entities are systems. Secondly, chemical systems are never at rest: if all chemical reactions in a system come to a halt, the system becomes a physical one. Thirdly, chemosystems have hardly any inertia, as shown by their quickness to respond to external inputs and to the cessation of the latter. (Mathematically: the equations of chemical kinetics are of the first order in the rates, whereas most physical equations of evolution are of the second order or higher.) Fourthly, controllers, such as catalyzers, play an important role in chemosystems, for even the H^+ and OH^- ions are catalyzers. On the other hand the only physical systems endowed with control mechanisms seem to be artificial. *Remark 2* We might have distinguished a system genus between biosystems and sociosystems, namely psychosystems. We have refrained from doing so from fear of encouraging the myth of disembodied minds. In our view psychosystems belong in the biosystem genus because they are animals endowed with a highly evolved nervous system. *Remark 3* We have not grouped technical systems, i.e. artifacts, together with any others, because they have ontological traits that set them apart: they are a product of human work and, as such, they bear the stamp of human intelligence and purposiveness as well as of social organization.

We compress the above remarks into

POSTULATE 6.4 At the present stage of the evolution of the universe there are five system genera: physical, chemical, biological, social, and technical. I.e. the family of system genera is $\mathcal{S} = \{S_1, S_2, S_3, S_4, S_5\}$.

The cautious clause about the present is a reminder that the higher kinds have not always existed (so far as we know), and may either become extinct or give rise to further system genera. Thus the exploration of outer space might reveal the existence of further system genera, and a nuclear holocaust would wipe out S_3, S_4 and S_5 on our planet.

6.3. *Novelty Sources*

Even assuming that the universe has always contained things of certain kinds, such as protons, there is little doubt that things of new kinds come into being every so often. I.e. at least part of the marvelous variety of the world is a product of change. Now, there are two main kinds of change: quantitative (e.g. motion) and qualitative (e.g. chemical combination). In the former case all of the axes of the state space of the thing are used; in the latter some new axes pop up and others drop out as change proceeds. However, even quantitative change may end up in qualitative newness, as in the case of high speed collisions of atomic nuclei, the reshuffling of the components of a system, and growth by accretion or multiplication. Let us take a look at reshuffling and accretion, which would seem to be unlikely emergence mechanisms.

A *reorganization* or *restructuring* is of course a change in the structure of a system, i.e. a change modifying some of the links among the system components even though it may not alter appreciably the intrinsic properties of the said components. Two simple examples are isomeric transitions (in an atomic nucleus or in a molecule) and institutional reorganizations without changes in personnel. In a closed system, repeated shuffling ends up in a state of equilibrium and disorder where no novelty can occur. On the other hand in an open system certain reorganizations accompanied by qualitative novelty and increase of order can occur. *Examples* The cooling of a liquid until it solidifies forming a crystal; the cooling of a metallic ring until it becomes superconducting; the magnetization of an iron bar; and the formation of patterns in fluids and in chemical systems. (Cf. Turing, 1952; Glansdorff and Prigogine, 1971; Haken, 1975.)

Another mechanism that may ensue in qualitative novelty is accretion or assembly. Thus stars and planets are believed to have formed by gravitational accretion of cosmic gas and dust. However, novelty is more likely to emerge along processes where heterogeneous things come together to form systems. This may occur even if "mistakes" – i.e. departures from the common pattern – are possible, that jeopardize the completion of the assembly process. Now, in principle assembly can proceed either in one stage – whether instantly or gradually – or in several. For example, a one stage assembly process may consist in the addition of one component per unit time; and a multiple stage assembly process may start with the formation of decamers out of monomers, proceeding with the formation of hectomers out of decamers, and so on. If there is a nonvanishing probability that each item (whether a monomer, a decamer, etc.) joins another in the "wrong" way – e.g. forming an unstable system – then the direct or one stage process is unlikely to yield systems of high complexity. As the number of intermediate stages in the synthesis of a complex system increases, the probability of departure from normality decreases and so the probability of success increases. (For the Crane-Rosen mathematical model of multiple stage assembly, see Rosen, 1970.) Since this result is independent of the nature of the units that get assembled, as well as of the bonds among them, we may assume that all complex systems, whether living or nonliving, have assembled by stages. This general principle of system architectonics deserves being incorporated into our ontology:

POSTULATE 6.5 The more complex a system, the more numerous the stages in the process of its assembly.

The dual of this hypothesis concerns the breakdown or dismantling of systems: it states that complex systems can decay in different ways, each way corresponding to the weakening of one set of bonds among the components. (Even comparatively simple things such as mu mesons can have multiple disintegration schemata.) In short we lay down

POSTULATE 6.6 The more complex a system, the more numerous its possible breakdown modes.

6.4. *Emergence*

Our next assumption is that every concrete system has assembled from, or with the help of, things in the same or lower order genera. In order to formulate this assumption with some precision we need

DEFINITION 6.1 Let $S = \{S_1, S_2, S_3, S_4, S_5\}$ be the family of system genera. Then S_i *precedes* S_j, or $S_i < S_j$ for short, iff things of genus S_i take part (either as components or as agents) in the assembly of every system in S_j.

Our hypothesis is

POSTULATE 6.7 For any $x \in S_j$ there is at least one $y \in S_i$, where $S_i < S_j$, such that y has taken part in the assembly of x.

Thus far we have only asserted that every system has been preceded by pre-existing things – which is the reciprocal of the holistic thesis that the whole precedes its parts. But we have not said exactly what precedes what. This we do now:

POSTULATE 6.8 The precedence relations among the system genera are

$$S_1 < S_2 < S_3 < S_4, S_5.$$

That is, the family of system genera is a tree rooted in S_1 and branching out at S_3 into S_4 and S_5: see Figure 6.1.

The precedence relation $<$ is a partial order relation. Hence the ordered $\mathscr{S} = \langle S, < \rangle$ is a partially ordered set. It may be called the *system structure of the world.* This is often mistaken for a hierarchy. Yet the difference between the two concepts is clear: whereas $\mathscr{S} = \langle S, < \rangle$ is the set of system genera ordered by the precedence (or emergence) relation, a hierarchy is a set of things (or of sets of things) ordered by a dominance relation. Besides, the thesis that the world has a hierarchical structure is usually a form of supernaturalism, and is not countenanced by science. On the other hand the thesis that the concrete systems in the world are distributed among S, and that higher genus systems have emerged from lower genera ones, is a component of a naturalist, systemist, pluralist, and dynamicist ontology.

6.5. *Systemism Supersedes Atomism and Holism*

The eight postulates proposed in the preceding subsections match with the assumptions made in the preceding chapters and crown our version of systemism. This ontology must not be mistaken for holism, or the romantic extolling of wholeness and emergence criticized in Ch. 1, Sec. 4.2. For, while holism claims that wholes and emergents must be accepted with "reverence" (Goethe) or "natural piety" (Alexander), systemism encourages attempts to analyze systems into their composition, environment, and structure, as well as to disclose the mechanisms of their formation and breakdown.

The demand for explanations of the way of systems should not be mis-

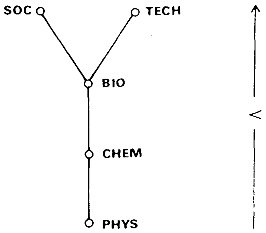

Fig. 6.1. The precedence relations among system genera.

taken for naive reductionism, i.e. the belief that all it takes to account for a whole is a knowledge of its parts. This belief is mistaken because systems possess properties absent from their components, hence not to be discovered by studying the latter in isolation from one another. Analysis is necessary but insufficient to account for the formation and persistence of systems: we must also study systems on their own level and interaction with things of different genera if we wish to understand them. This is what the theories of systems of various kinds – physical, chemical, biological, social, and technical – are all about.

The philosophy that combines an acknowledgment of emergence with the thesis that emergence is explainable and predictable within bounds may be called *rational emergentism.* This philosophy, foreshadowed by Sellars (1922), supersedes both atomism (though not its allegiance to science) and holism (though not its insistence on emergence), and it incorporates a critical realist theory of knowledge – of which more in the next two volumes of this *Treatise.*

6.6. *Synopsis*

It is closing time. We close by characterizing the ontology presented in this volume and its companion, *The Furniture of the World*, in terms of a few traditional *isms.* (A single *ism* is bad because it is one-sides and rigid. Many-sidedness and flexibility can be achieved only by a system of matching *isms.*)

Our ontology endorses

(i) *naturalism* or *materialism*, for it countenances only material existents and discounts autonomous ideas, ghosts, and the like; but *not physicalism* (or *mechanism*), as this denies that all things are physical entities;

(ii) *systemism*, for it holds that every thing is either a system or a component of one; but *not holism*, as it rejects the myths that the whole is incomprehensible, prior to its components, and superior to them;

(iii) *pluralism* as regards the variety of things and processes, hence the plurality of kinds of thing and laws; and also *monism* as regards the substance that possesses properties and undergoes change (namely matter) as well as the number of worlds (just one);

(iv) *emergentism* with regard to novelty, for it holds that, while some bulk properties of systems are resultant, others are emergent; but *not irrationalism* with regard to the possibility of explaining and predicting emergence;

(v) *dynamicism*, for it assumes that every thing is in flux in some respect or other; but *not dialectics*, for it rejects the tenets that every thing is a unity of opposites, and that every change consists in or is caused by some strife or ontic contradiction;

(vi) *evolutionism* with regard to the formation of systems of new kinds, for it maintains that new systems pop up all the time and are selected by their environment; but *neither gradualism nor saltationism*, for it recognizes both smooth changes and leaps;

(vii) *determinism* with regard to events and processes, by holding all of them to be lawful and none of them to come out of the blue or disappear without leaving traces; but *not causalism*, for it recognizes randomness and goal striving as types of process alongside causal ones;

(viii) *biosystemism* with regard to life, for it regards organisms as material systems that, though composed of chemosystems, have properties not found on other levels; but *neither vitalism nor machinism nor mechanism*;

(ix) *psychosystemism* with regard to mind, for it holds that mental functions are emergent activities (processes) of complex neural systems; but *neither eliminative nor reductive materialism*, for it affirms that the mental, though explainable with the help of physical, chemical, biological, and social premises, is emergent;

(x) *sociosystemism* with regard to society, for it claims that society is a system composed of subsystems (economy, culture, polity, etc.), and possessing properties (such as stratification and political stability) that no individual has; hence *neither individualism nor collectivism*, *neither idealism nor vulgar materialism*.

The reader accustomed to dwell in a single *ism* or in none is likely to throw up his hands in despair at the multiplicity of *isms* embraced by our ontology. Let this be said in defense of such multiplicity. First, it is possible to synthesize a variety of philosophical *isms* provided they are not mutually inconsistent – i.e. provided the result is a coherent conceptual system rather than an eclectic bag. (We have tried to secure consistency by adopting the axiomatic format.) Second, it is necessary to adopt (and elaborate) a number of philosophical *isms* to account for the variety and mutability of reality – provided the various theses harmonize with science. Third, tradition can be avoided only at the risk of unfairness and ignorance: rather than dismiss our philosophical legacy altogether, we should try and enrich it.

APPENDIX A

SYSTEM MODELS

This Appendix is a review and philosophical analysis of some simple yet serviceable models of concrete systems regardless of the nature of their components, hence of the kind of bonds among them. The aims of this presentation are (*a*) to clarify some of the key concepts employed in the text, (*b*) to supply a stock of examples, and (*c*) to discuss some problems in the as yet immature philosophy of systems science. For details see Ashby (1956), Athans and Falb (1966), Dorf (1974), Harrison (1965), Klir (1969), Klir and Valach (1967), Lange (1965), Padulo and Arbib (1974), and Zadeh and Desoer (1963).

1. INPUT-OUTPUT MODELS

1.1. *The Black Box*

The simplest (i.e. poorest) model of a thing one can think of is a black box that does not interact with its environment. ('Black' because it has no structure or we do not care to disclose it.) This, the bare black box model, ignores both the internal structure of the thing modeled and its actions upon other things as well as the actions its environment exerts on it. Despite its poverty, such a model can be endowed with a number of attributes assumed to represent properties of the real thing. The classical particle in free motion and the totally isolated thermostatic system are cases in point.

Next in order of complexity comes the black box proper, fitted with terminals connecting it to its environment – which is in turn treated globally or as composed of other black boxes. The simplest black box has just one input terminal, representing either the action (in a given respect) of the environment on the thing, or the thing's reaction (in the same or a different respect) upon the environment. The former model represents a passive thing, the latter an active one, and both are called *monopoles*. Since in reality there are neither totally passive nor fully active systems, the monopole model is adequate only in extreme cases and when a single property is considered.

A more realistic model of a thing is of course the black box fitted with both input and output terminals, i.e. sensitive to (a part of) its environment and in turn reacting on (some features of) the latter. We call this the *complete black box*, or *black box* for short. The simplest complete black box is sensitive to stimuli of just one kind and accepts just one stimulus at a time – i.e. has a single input terminal; and it also has a single output terminal, i.e. acts just in one fashion on its environment and performs one action at a time. This, the simplest black box, is called a *dipole*. Any more complex black box is called a *multipole*: it is equipped with a certain number of input terminals of the same or different kinds. See Figure A1. We shall concentrate our attention on the dipole, which is the building block of every other input-output model of a system.

From a strictly formal point of view a dipole is just a double entry table of items (e.g. numbers), or set of ordered pairs $\langle u, v\rangle$, where $u \in U$ is an input value and $v \in V$ the corresponding output value. In other words, a black box of this kind boils down to a binary relation f (perhaps a function) with graph or extension $\mathscr{E}(f) \subset U \times V$, where U is the collection of possible inputs and V that of possible outputs. (This is what Mesarović (1968) calls a *general system*. But it is a model of a system and moreover not completely general, for it neglects the internal structure of the system.)

The simplest of all such model systems, i.e. the dipole, has inputs and outputs of the yes or no type: i.e. the terminals are either on (value 1) or off (value 0). That is, $U = V = \mathbb{2} = \{0, 1\}$, and $f\colon \mathbb{2} \to \mathbb{2}$ is the *transfer function*. *Example 1* The conformist box: $f(0) = 0, f(1) = 1$. *Example 2* The nonconformist box: $f(0) = 1, f(1) = 0$. *Example 3* The capricious (yet not chaotic) or stochastic box: $Pr(0 \mid 0) = p > 0$, $Pr(1 \mid 0) = 1 - p$, $Pr(0 \mid 1) = q > 0$, $Pr(1 \mid 1) = 1 - q$, where p is the probability of response 0 to stimulus 0, and similarly for q. (Note the difference between the stochastic box, characterized by constant values of p and q, hence statistically reliable, and a totally chaotic box, i.e. one with no transfer function.) All three boxes are coarse models of a specialist; the third models the creative type.

Other black boxes accept continuous streams of stimuli and deliver

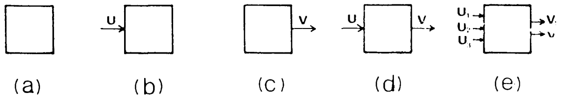

Fig. A1. (*a*) The bare black box. (*b*) The passive monopole, or system without outputs. (*c*) The spontaneous monopole, or system without inputs. (*d*) The dipole, or simplest complete black box. (*e*) The reactive multipole.

continuous streams of outputs. That is, their transfer functions are smooth functions of time. *Example 1* Differentiator. The state of the system at time $t \in T$ is the ordered pair $\langle u(t), \dot{u}(t)\rangle$, where $u : T \to \mathbb{R}$ and $\dot{u}$ is the rate of change of u. The state space of the system is $S = U \times V$, where U is the image of u and V that of $v = \dot{u}$. *Example 2* Delay line. Here $v(t) = u(t - \delta)$ with $\delta > 0$. I.e. the current output equals the input at the earlier time $t - \delta$. The state space is $S = U \times \{u(t - \delta) \mid t \in T\}$.

In the last two examples the input and output values were parametrized by time – i.e. U and V were construed as the images of time-dependent functions. In general the output value $v(t)$ at time t will depend not only on the current value of the input (as in Example 1) but also on some or even all of the inputs accepted earlier by the system (as in Example 2). I.e. in general the system will have *memory* (or be *hereditary*). A fairly general input–output relation covering all such cases for the dipole, and easily generalizable to the multipole, is

$$v(t) = \int_{-\infty}^{t} d\tau\, M(t, \tau) F(u(\tau)),$$

where M summarizes the structure of the box (Bunge, 1963a). The domain of integration, which stops at t, has been chosen to conform with the antecedence principle (Postulate 6.12 in Vol. 3, Ch. 6, Sec. 5.3). If M is a delta function, then the box is memoriless. If F is a linear function then the above represents a linear dipole. In a great many cases M does not depend on t but only on the past (if at all), and $F(u(\tau)) = u(t - \delta)$, where δ is a time lag. In such cases the integral is the convolution of the two functions, and the mathematics is greatly simplified.

1.2. *Connecting Black Boxes*

Strictly speaking a black box is a suitable model not of a system but rather of a system component. In many cases a system can be adequately modeled as an assembly of black boxes connected in a suitable way. The basic modes of coupling are as follows.

(i) *Series coupling*: see Figure A2a. If the two component boxes are characterized by the transfer functions $f : U \to V$ and $g : V \to W$, then the resulting box is characterized by the composition $h = f \circ g$ with values $w = g(f(u))$. Note that, in general, function composition is not commutative; thus g might filter out all stimuli except those in a certain set, while

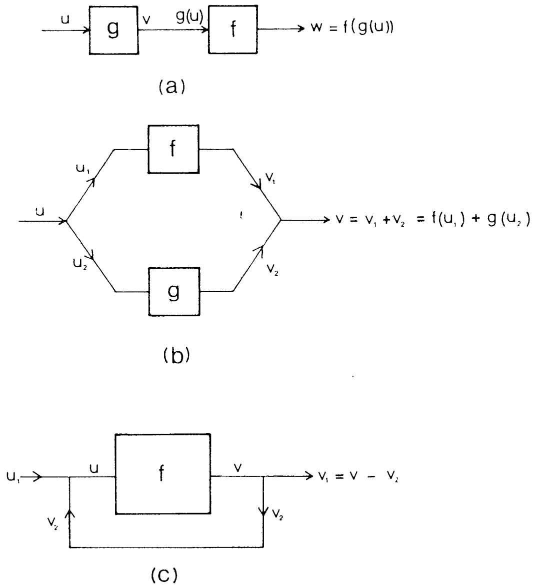

Fig. A2. (*a*) Series combination of two dipoles. Example: cloth manufacturer *g* supplies clothing manufacturer *f*. (*b*) Parallel connection of two dipoles. Example: two branches of a cloth manufacturing concern. (*c*) Feedback coupling (or self interconnection). Example: blood pressure control system.

f could just delay the responses. Example: a (living or industrial) plant *f* that manufactures materials produced by another plant *g*.

(ii) *Parallel coupling*: see Figure A2b. The input is shared by the two components and the output is the sum of the partial outputs. I.e. $u = u_1 + u_2$ and $v = f(u_1) + g(u_2)$. Example: two industrial plants that consume and produce similar goods at the same time.

(iii) *Feedback coupling*: see Figure A2c. The system is coupled to itself in such a way that part of its output is fed back as an input. That is, $v = f(u) = v_1 + v_2$ and $u = u_1 + v_2$, where now u_1 is the external input (stimulus) and v_2 the net output (response) whereas v_2 is the correcting feedback.

By combining tandem, parallel and feedback couplings one can synthesize any complex system of the input–output type. An assemblage of interconnected black boxes is not a black box itself but has emergent properties. One way of representing the resulting system is by means of the list of all the transfer functions characterizing its components when inter-connected, i.e.

$$\mathbb{F} = \langle f_1, f_2, \dots, f_n \rangle, \quad \text{where} \quad f_i\colon U_i \longrightarrow V_i.$$

While some of these functions represent external terminals (or *exogenous* variables), others represent internal terminals (or *endogenous* variables).

Input–output models are used in a number of fields, from thermodynamics and electrical engineering (the two historical sources) to biology, psychology, and social science. (Most of what goes under the name of *systems analysis* consists in building such models.) Their success has fostered the beliefs that (*a*) every system can be fully modeled by an input–output model, and (*b*) the world as a whole is a supersystem composed of multipoles. But these are illusions. (The technologist's sweet dream is the metaphysician's nightmare.) Firstly, there are plenty of systems without any recognizable inputs and outputs: just think of a radio wave. Secondly, in many cases we need to know the spatial locations of the parts of a system: time is not enough. (Think again of a radio wave, or of a brain, or of a city.) An input-output analysis, though practicable and useful in many areas – particularly in technology – is much too poor and is bound to be eventually supplemented or even superseded by a deeper and more detailed model. Thus thermodynamics is supplemented by statistical mechanics, electric network theory by electrodynamics, stimulus-response psychology by psychobiology, and so on. (For an evaluation of black boxes and a criticism of blackboxist philosophy see Bunge (1964).)

1.3. *Control System*

A control system is composed of two subsystems: an ordinary or controlled system and a controlling system, i.e. one that controls or regulates the output of the former. The controlling system acts by absorbing part of the total output and feeding it back into the system in such a way that the effective input itself is modified, and the net output differs from that of the uncontrolled system. The controlling system has two main components: the *imbalance* (or *error*) *detector* and the *response mechanism.* The latter is driven by the former in proportion to the deviation of the current state of the controlled system from the set point or ideal state or "goal". In other words, the detector is activated (has an output) just in case the controlled system is in a state other than the set point. See Figure A3.

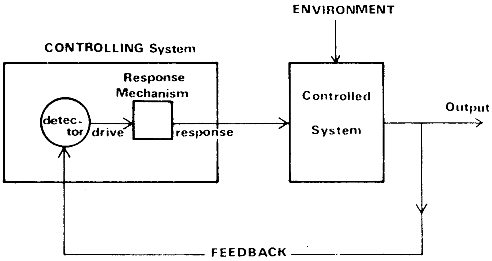

Fig. A3. Feedback control system. The detector compares the output (actual state) of the controlled system and, if it differs from the set point, drives the response or corrective device, which acts on the controlled system to correct the imbalance.

The study of specific control systems belongs to the special sciences, such as mechanical and electrical engineering, biochemistry, physiology, economics, and politology. And the scientific study of the features common to all control systems, regardless of their composition, is of course cybernetics (Wiener, 1948). Cybernetics was born in advanced engineering but, since it is stuff-free (i.e. independent of the kind of material), it assumes no special physical, chemical, biological, or social laws, so it covers all levels. It is therefore a chapter of the general theory of systems as well as of scientific ontology.

The supersystem composed by the controlled and the controlling systems can be described as follows. The total state function of the supersystem is

$$\mathbb{F} = \langle F_1, F_2, \dots, F_p, F_{p+1}, F_{p+2}, \dots, F_n \rangle : T \longrightarrow \mathbb{R}^n,$$

where the first p coordinates are the so-called *state variables* and the remaining $n - p$ components the *control variables*. These components are subjected to three sets of conditions:

(i) *constraints* on the state variables (e.g. their values must lie within a certain region of the state space);

(ii) *control* or *steering conditions* specifying the manner in which the control variables affect the state variables, e.g.

$$\dot{F}_i = g_i(\mathbb{F}, t) \quad \text{for } 1 \leq i \leq p;$$

(iii) *optimization conditions* on certain state variables (e.g. minimization of energy consumption, or maximization of the rate of production of some substance).

A good way to get a feel for cybernetics is to study a simple control system such as an integrator (e.g. area calculator) with feedback control. In the absence of a controller and if the system is initially inert, the input-output equation is

$$\dot{v} = u, \quad \text{with} \quad v(t) = 0 \quad \text{for } t \leq 0.$$

This entails

$$v(t) = \int_0^t d\tau \, u(\tau),$$

so that the system integrates the input. In particular, a constant input

$$u(t) = H(t) = \begin{cases} a \in \mathbb{R}^+ & \text{for } t \geq 0 \\ 0 & \text{for } t < 0 \end{cases}$$

is converted into $v(t) = at$. Obviously this output, unless checked, gets eventually out of hand. This can be prevented by coupling the integrator to a controller that diverts part of the output and sends it back to the input terminal, so that a closed loop results: see Figure A4.

In the simplest case the output fraction $kv(t)$, where $|k| < 1$, is fed back diminished but without distortion, so that the input–output equation reads now

$$v = u + kv, \quad \text{with} \quad -1 < k < 1.$$

If $k > 0$, the feedback is *positive*, i.e. it enhances the effect of the input, so that the system may become uncontrollable. The feedback is *negative*, and results in a stable system, if it checks the input, i.e. $k < 0$. The solutions for the case of the constant input $u = H(t)$ applied for $t > 0$ are

(i) for $k > 0$ (*positive feedback*)

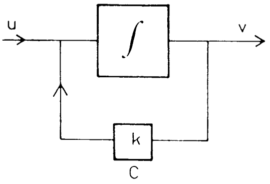

Fig. A4. Integrator with feedback control. The effect of the control subsystem C is to convert a constant input into either an exponentially growing response (for $k > 0$) or an exponentially decaying one (for $k < 0$).

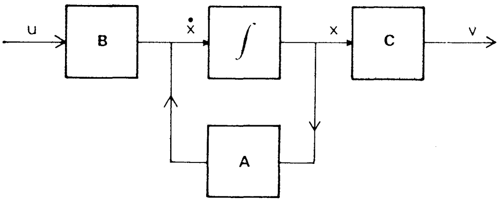

Fig. A5. Linear control system.

$$v(t) = \frac{a}{k}(\exp(kt) - 1) \quad \text{exponential growth}$$

(ii) for $k < 0$ (*negative feedback*)

$$v(t) = \frac{a}{|k|}(1 - \exp(-|k|t)) \quad \text{decelerated growth approaching the target value } a/|k|$$

Note that both the controlled and the controlling subsystems have been treated as black boxes: their mechanisms have not been specified. Nor could they without roping in definite law statements (physical, biological, or what have you).

The above example illustrates the black box model of a control system. In most cases such a model is insufficient and a grey box model is required, i.e. one involving not only an input vector u and an output vector v but also an (internal) state vector x. The simplest example of such a model of a control system is, of course, the linear system

$$\dot{x} = Ax + Bu, \qquad v = Cx,$$

where the state matrix A, the input matrix B, and the output matrix C are constant. The corresponding block diagram is shown in Figure A5.

1.4. *Stability and Breakdown*

As we saw in Sec. 1.3, feedback can be positive (enhancing) or negative (checking). If negative, feedback may correct misalignments. If it does, the corresponding system is said to be *self-stabilizing*, for in such case all the components of its state vector remain bounded all the time. See Figure A6.

Equilibrium can of course be static or dynamic. In the former case nothing changes, so that the representative point in the state space remains

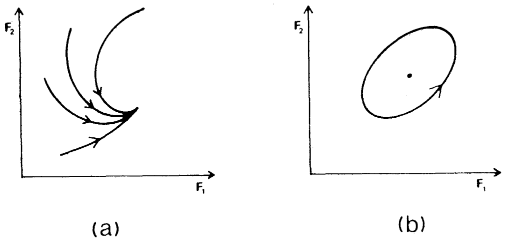

Fig. A6. Two kinds of stable orbits in state space. (a) Spiral approach to static equilibrium. (b) Stationary orbit.

fixed. (But of course no system remains forever in a state of static equilibrium for, even if it is internally stable, every system is subjected to disruptive external influences.) In the case of dynamic equilibrium the trajectories remain within a certain limited region of the state space. The departures from equilibrium may be regular (e.g. sinusoidal oscillations about a point) or irregular – in which case they are called *fluctuations* or *stochastic oscillations*. A system may oscillate around an equilibrium position, whether regularly or irregularly, either spontaneously (self-excited oscillations) or under the action of its environment (forced oscillations). If the oscillation amplitude increases in the course of time instead of remaining bounded or fading out (damping), the system is unstable and eventually breaks down.

If the ongoing existence of a system depends critically on its keeping its properties within certain bounds, then it will have more chances of "survival" if it is self-stabilizing than in any other case. But of course even a system of this kind may be subjected to such strong external disturbances that they drive it permanently far from equilibrium and eventually into breakdown. If the parameters of the controlling components (e.g. thresholds, delays, stiffness) are rigid (constant), then the system may not be able to withstand any large inputs – i.e. may not adapt to the new circumstances. The only chance a system has to withstand strong environmental impacts, within bounds, is by varying some of its parameters as required by the occasion – e.g. to raise some of its thresholds, to lengthen some of its delays, or to decrease its stiffness, or to vary whatever other parameters in such a manner that its wholeness or integrity be preserved. A "plastic" system of this kind is capable of evaluating its own performance and adjusting some of its properties in such a way that its outputs be kept within the stability limits. Far from being a passive toy of its environment, such a system adapts itself actively to it and thus manages to endure. Because such systems are of paramount importance in the life sciences and in the social sciences, not to mention technology, they deserve a name of their own:

DEFINITION A1 A control system of the negative feedback type that changes some of its parameters in such a way that it remains stable in the presence of a changing environment is called a *self-governed, self-controlled, autonomic, adaptive*, or *plastic* system.

What happens if a system becomes unstable? There are two possibilities: if rigid it suffers *structural breakdown*, i.e. destruction. Nuclear disintegration and fission, the blowing up of a section of a network of any kind, the death of an organism, and the extinction of a biopopulation or an ecosystem, illustrate structural breakdown. On the other hand if the system is plastic it is said to suffer *functional breakdown*, i.e. it becomes a stable system of another kind. For example, an insulator subjected to a voltage above a certain point becomes a conductor; a man in a state of shock may lose some haunting memories; a society may become viable by modernizing its technology or getting rid of its parasites. In any case instability, usually dreaded by the engineer, is of interest to the scientist and the philosopher because it is often at the root of radical novelty. In other words, functional breakdown may result in structural buildup or morphogenesis.

2. GREY BOX MODELS

2.1. *Generalities*

Take a black box and observe or conjecture its internal states without however disclosing the mechanism that makes it tick: you have a grey box. Psychologists say that an *intervening variable* has been added to the stimulus-response pairs, and that the new variable is not a "hypothetical construct" but a mere formal link between inputs and outputs. But if the intervening variable is interpreted as representing the mechanism that transforms inputs into outputs, then instead of a grey box we have a dynamical box (Appendix B, Sec. 1). A grey box is then midway in depth between a black box and a translucid box or mechanismic model. We may picture it as a box equipped with a ladder every rung of which represents a state of the system: see Figure A7.

Of all the grey box theories the simplest is perhaps automata theory (Arbib, 1969; Ginsburg, 1962; Guinzburg, 1968; Harrison, 1965; McNaughton, 1961; Rabin and Scott, 1959; Rabin, 1963). As idealized by this theory, an automaton is a one component system admitting inputs of some kind (e.g. punched cards) and producing outputs of the same or of a different kind, such as printed symbols. The automaton jumps from one state to another in response to, or at least under the influence of, the inputs it accepts. All three – inputs, internal states, and outputs – are assumed to be denumerable. In short, an automaton is a discrete and sequential system. If lacking in spontaneity, i.e. acting only under external compulsion, the automaton is called *deterministic.* If inputs and internal states determine only output probabilities, the automaton is called *probabilistic.* Deterministic automata are of interest mainly in technology, where highly reliable systems are desirable. Probabilistic automata are of greater scientific and philosophical interest, for natural systems, such as brains and communities, are endowed with some spontaneity and seem to have strong stochastic components.

Automata are of greater interest than black box models because, unlike the latter, they take into account not only the behavior but also the internal states of the system. Consequently an automaton model can succeed (i.e. be true) where a black box model must fail (i.e. be false), namely (*a*) when a stimulus elicits different responses depending on the state of the system, or (*b*) when the system has spontaneous (uncaused) outputs. But of course automata models share with black box models the lack of concern with the specific nature of the thing modeled and even the spatial configuration of its components. In other words automata theory is a global (but not holistic), stuff-free (but not ghostly), atopic (nonspatial) and achronic (nontemporal) theory. Being so extremely poor, it is applicable to all

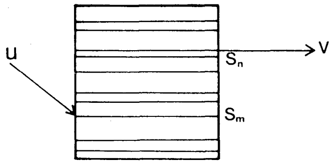

Fig. A7. Transition of system from state s_m to state s_n under the influence of input u.

kinds of system. (Perhaps for this reason von Neumann, 1951, mistook it for a chapter of formal logic.)

All information processing systems may be regarded, at least to a first approximation, as automata: nervous systems, servomechanisms, computers, TV networks, and so on. Therefore the referent of automata theory is not a narrow species of system but the entire genus of information processing systems, whether physical, chemical, living or social. And because the theory is concerned with certain traits of concrete systems, it is not a formal theory but a factual one. Indeed it provides an exact and simple (hence also superficial) model of a system interacting with its environment regardless of any specific features of interest to the special sciences – such as the kinds of material it is built from and the way it is energized. For this reason automata theory belongs not only in advanced technology but also in ontology. Let us therefore take a quick look at it.

2.2. *Deterministic Automata*

Automata theory presupposes only ordinary logic, the concepts of set and function, and some abstract algebra: it does not rest on any body of factual knowledge; in particular it contains no law statement borrowed from other theories. The specific defining (primitive) concepts of the theory of deterministic automata are collected in Table A1.

The above concepts are interrelated and made precise by the axiomatic

TABLE A1

Basic concepts of the theory of deterministic automata

Symbol	Mathematical nature	Factual interpretation
Σ	Set	Set of distinct unit inputs
Ω	Set	Set of distinct unit outputs
σ_0	Individual	Null input or pause
$\circ$	Binary operation	Concatenation
S	Set	State space
M	Function	Transition (next state) function
N	Function	Output function
s_0	Individual	Initial state
F	Set	Set of final states

DEFINITION A2 The structure $\mathscr{A} = \langle \Sigma, \Omega, \sigma_0, \circ, S, M, N, s_0, F \rangle$ represents a *finite deterministic automaton* (or *sequential machine with output*) A iff

(i) $\Sigma = \{\sigma_0, \sigma_1, \ldots, \sigma_k\}$, called the *input alphabet*, is a nonempty set with $k + 1$ elements called *letters*, every one of which represents a unit input on A from its environment;

(ii) Ω, called the *output alphabet*, is a set with two elements: 0 and 1, where 0 represents the absence of an output and 1 a unitary output;

(iii) let Σ^* be the set of finite concatenations, called *tapes*, of elements of Σ (i.e. letters), and let $\sigma_0 \in \Sigma$ be such that, for every tape $x \in \Sigma^*$, $\sigma_0 x = x\sigma_0 = x$. Likewise let Ω^* be the set of finite concatenations of elements of Ω, with $0 \in \Omega$ such that, for every $y \in \Omega^*$, $0y = y0 = y$. The structures $\langle \Sigma^*, \circ, \sigma_0 \rangle$ and $\langle \Omega^*, \circ, 0 \rangle$ are free monoids; $\circ$ represents the combination or concatenation of successive inputs to or outputs of A;

(iv) S, called the *state space* of A, is a finite nonempty set with n elements, where $n > 1$; every member of S represents an internal state of A;

(v) the function M: $S \times \Sigma^* \to S$ is called the *transition* (or *next state*) function; if $s \in S$ and $x \in \Sigma^*$, then $M(s, x) \in S$ represents the state A goes into when A, while in state s, admits input x;

(vi) the function N: $S \times \Sigma^* \to \Omega^*$ is called the *output function* and is such that $N(f, x) = 1 \in \Omega^*$ for every $f \in F \subset S$ and every $x \in \Sigma^*$, where $N(s, x)$ represents the output of A when acted on by the input $x \in \Sigma^*$ while in state s;

(vii) s_0 is a distinguished element of S representing the initial internal state of A;

(viii) F is a nonempty set included in the state space S, and every member f of F represents a final state of A;

(ix) A makes no spontaneous transitions; i.e. the null input has no effect: for every s in S, $M(s, \sigma_0) = s$;

(x) the internal states form sequences, i.e. the effect of a compound input $x \circ y$, where $x, y \in \Sigma^*$, equals the effect of the second input acting on the automaton in the state to which the first input carried it:

$$M(s, x \circ y) = M(M(s, x), y).$$

The last two assumptions are the essential components of Definition A2. They characterize an entire class of transition or next state functions, and state that a deterministic automaton operates only under external stimulation, sequentially, and in a determinate fashion. Nothing is said about the precise structure of the system, let alone its physics and chemistry: this is why automata theory has such a wide range of applications.

Examples The tables and state transition diagrams in Figure A 8 characterize two different automata with the same internal states reacting differently to the same unit inputs σ_1 and σ_2. They may thus represent some trait of the behavior of two different insects confronted with the same circumstances.

	s_0	s_1	s_2
$M_1(s, \sigma_1)$	s_1	s_2	s_1
$M_1(s, \sigma_2)$	s_2	s_0	s_2
$M_2(s, \sigma_1)$	s_0	s_2	s_2
$M_2(s, \sigma_2)$	s_1	s_0	s_0

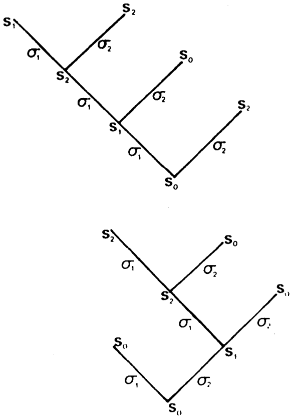

Fig. A8. Two different three state automata, each characterized by a different transition function (M_1 and M_2 respectively), subjected to the same stimuli.

In order to exhibit some consequences of the axiomatic definition of a deterministic automaton we need a couple of conventions. First,

DEFINITION A3 Let $\mathscr{A} = \langle \Sigma, \Omega, \sigma_0, \circ, S, M, N, s_0, F \rangle$ represent an automaton A. Then

(i) the restriction of the transition function M to s_0 is called the *response function*: $rp(x) = M(s_0, x)$, for $x \in \Sigma^*$;

(ii) a state $s \in S$ of A is *accessible* iff there is some input $x \in \Sigma^*$ such that $s = rp(x)$ – otherwise s is *inaccessible*;

(iii) a tape $x \in \Sigma^*$ is *accepted* (or *recognized*) by A iff $rp(x) \in F$ (i.e. if x has an overt effect when acting on A in s_0);

(iv) the *behavior* of A is the set of all the tapes accepted (or recognized) by A: $\beta(A) =_{df} \{x \in \Sigma^* \mid rp(x) \in F\}$;

(v) two automata A and A' are *behaviorally identical* iff $\beta(A) = \beta(A')$.

Note the difference between the above notion of behavior and that used in the so-called behavioral sciences.

And now a few typical consequences. Firstly

THEOREM A1 If two inputs $x, y \in \Sigma^*$ have the same effect, then the effects of the compound inputs xz and yz are the same for an arbitrary tape $z \in \Sigma^*$. I.e. for all states $s \in S$ and all inputs $x, y, z \in \Sigma^*$,

$$M(s, x) = M(s, y) \Rightarrow M(s, x \circ z) = M(s, y \circ z).$$

COROLLARY A1 For any tapes $x, y, z \in \Sigma^*$,

$$rp(x) = rp(y) \Rightarrow rp(xz) = rp(yz).$$

THEOREM A2 Every accessible state of an automaton which is the response to an input whose length is at least equal to the number of states of the system, can also be produced by a shorter input. In other words: If A has n states and if $s = rp(x)$ is an accessible state of A for some tape x composed of $m \geq n$ unit letters, then there exists another tape y such that $rp(y) = s$ and whose length is smaller than m.

THEOREM A3 Every accessible state of an automaton with n states is the response to some input of length smaller than n.

Let us now define the concept of automata analogy:

DEFINITION A4 Let $\mathscr{A} = \langle \Sigma, \Omega, \sigma_0, \circ, S, M, N, s_0, F \rangle$ and $A' = \langle \Sigma', \Omega', \sigma_0', \circ, S', M', N', s_0', F' \rangle$ represent finite automata A and A' respectively. Then

(i) A is *homomorphic* to A' iff there exists a mapping φ from $\mathscr{A}$ to $\mathscr{A}'$ such that

(*a*) $\varphi: \Sigma^* \cup S \to \Sigma'^* \cup S'$;

(b) for every u in $\Sigma^* \cup S$: if $u \in S$ then $\varphi(u) \in S'$;

(c) $\varphi(s_0) = s_0'$;

(d) for every t in $\Sigma^* \cup S$: if $t \in F$ then $\varphi(t) \in F'$;

(e) for every s in S and every σ in Σ: $\varphi(M(s, \sigma)) = M'(\varphi(s), \varphi(\sigma))$, $\varphi(N(s, \sigma)) = N'(\varphi(s), \varphi(\sigma))$;

(ii) A and A' are *isomorphic* iff φ is bijective;

(iii) A and A' are *structurally equivalent* iff they isomorphic;

(iv) the set of all automata isomorphic to a given automaton A is called the *structure type* of A.

It can be proved that, if there exists a homomorphism from one automaton to another, then it is unique. (The same holds, *a fortiori*, for isomorphisms.) The necessary and sufficient conditions for homomorphism and isomorphism are formulated in terms of

DEFINITION A5 An *equiresponse* relation $\sim_A$ on the set Σ^* of tapes is a binary relation on Σ^* such that, for any $x, y \in \Sigma^*$,

$$x \sim_A y \text{ iff } rp(x) = rp(y).$$

By using Definition A4 of homomorphism it is possible to prove

THEOREM A4 Let A and A' be automata. Then there is a homomorphism from A into A' iff the extension of $\sim_A$ is included in that of $\sim_{A'}$ and the behavior of A is included in that of A'.

COROLLARY A2 Two automata are isomorphic iff the extensions of their equiresponse relations coincide and their behaviors are the same.

2.3. *Probabilistic Automata*

The theory of probabilistic automata has the same formal background as that of deterministic automata plus elementary (discrete) probability theory. Its foundations are compressed into

DEFINTION A6 The structure $\mathscr{P} = \langle \Sigma, \Omega, \sigma_0, \circ, S, M, N, s_0, F \rangle$ represents a *finite probabilistic automaton P* iff all the coordinates of $\mathscr{P}$ but M satisfy the clauses of Definition $A2$, and M is now a function from $S \times \Sigma$ into the real interval $[0, 1]^{n+1}$, called the *table of transition probabilities*, such that, for every state $s \in S$ and letter $\sigma \in \Sigma$,

$$M(s, \sigma) = \langle p_0(s, \sigma), p_1(s, \sigma), \dots, p_n(s, \sigma) \rangle$$

where

(i) the $p_i(s, \sigma)$, for $i = 0, 1, \dots, n$, are probabilities, subject to the condition

$$\Sigma_i \, p_i(s, \sigma) = 1 \quad \text{for all } \sigma \in \Sigma;$$

(ii) $p_i(s, \sigma)$, for $i = 0, 1, \dots, n$, measures the strength of the disposition or propensity for the automaton P, when in state s, acted on by a unit stimulus σ, to jump into the state $s_i \in S$.

Since the transition function is now a probability, we have relinquished not only the determinate behavior of the system but also the serial or sequential character of its operations. The theory describes then the possible rather than the actual behavior of the system. How this is done can be gathered from what follows.

So far we have dealt only with unit inputs or letters. In order to deal with tapes or words we need one more item of notation:

DEFINITION A7 The *stochastic matrix* associated with a unit input $\sigma \in \Sigma$ is

$$P(\sigma) = \|p_j(s_i, \sigma)\|, \quad \text{with } i, j = 0, 1, \ldots, n.$$

The main result concerning the probability associated with a tape or word expresses the statistical independence of the effects of its components:

THEOREM A5 The stochastic matrix of an input $x = \sigma_p \sigma_q \cdots \sigma_r$ equals the product of the stochastic matrices of the unit components of the tape:

$$P(\sigma_p \sigma_q \cdots \sigma_r) \equiv \|p_j(s_i, \sigma_p \sigma_q \ldots \sigma_r)\| = P(\sigma_p) \cdot P(\sigma_q) \cdots P(\sigma_r).$$

DEFINITION A8 Let $\mathscr{P} = \langle \Sigma, \Omega, \sigma_0, \circ, S, M, N, s_0, F \rangle$ represent an automaton P and let $I = \{i_0, i_1, \ldots, i_r\} \subset \mathbb{N}$ be an index set used to label the final states, i.e. set $F = \{s_{i_0}, s_{i_0}, \ldots s_{i_r}\}$. The *probability of tape* $x \in \Sigma^*$ *being accepted* (recognized) by P when in s_0 is

$$p(x) = \sum_{i \in I} p_i(s_0, x).$$

Example Let $\Sigma = \{\sigma_0, \sigma_1, \sigma_2\}$, $S = \{s_0, s_1\}$, $F = \{s_1\}$, and assume the stochastic matrices

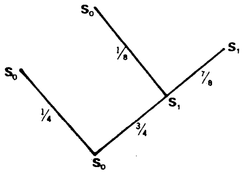
$$P(\sigma_1) = \left\| \begin{matrix} 1 & 0 \\ \frac{1}{2} & \frac{1}{2} \end{matrix} \right\| \qquad P(\sigma_2) = \left\| \begin{matrix} \frac{1}{2} & \frac{1}{2} \\ 0 & 1 \end{matrix} \right\|.$$

Then the table of transition probabilities for the tape $x = \sigma_1 \sigma_2 \sigma_2$ is

$$P(\sigma_1 \sigma_2 \sigma_2) = P(\sigma_1) \cdot P(\sigma_2) \cdot P(\sigma_2) = \left\| \begin{matrix} \frac{1}{4} & \frac{3}{4} \\ \frac{1}{8} & \frac{7}{8} \end{matrix} \right\|$$

$$= \left\| \begin{matrix} p_0(s_0, x) & p_1(s_0, x) \\ p_0(s_1, x) & p_1(s_1, x) \end{matrix} \right\|.$$

The corresponding diagram in the state space is



Only the probable set of behaviors of a probabilistic automaton can be computed: its actual behavior can only be described after the event. However, if the various transition probabilities are markedly different from one another, it is possible to anticipate the most probable behavior of an automaton by taking into account only those inputs that have a fair chance of being accepted, and ignoring all others. More precisely, one can choose a real number comprised between 0 and 1, called the *cutpoint*, below which all probabilities can be neglected – at a risk of course. In other words, one can use

DEFINITION A9 Let P be a probabilistic automaton and let r be a real number such that $0 \leq r \leq 1$. Then *the most probable behavior* above (the cutpoint) r is

$$\beta_r(P) = \{x \in \Sigma^* \mid p\,(x) > r\}.$$

The relation between probabilistic and deterministic automata, as regards their behavior, is given by

THEOREM A6 P is a deterministic automaton iff $\beta_r(p) = \beta(P)$ for any r such that $0 \leq r < 1$.

This is but an instance of an important metatheorem that has no known proof, namely: *Every stochastic theory includes a deterministic subtheory.*

2.4. *Information Systems*

Our last example of grey box models will be the information system. The signals impinging upon an automaton, whether deterministic or probabilistic, drive it from one state to the next, either invariably or with a certain probability, without altering the set of its possible final states. On the other hand if certain inputs can alter – e.g. expand or shrink – the subset of final states in the state space of a system, then the latter does not qualify as an automaton but does qualify as an *information system*. That is, an information system is one that can gain or lose final states in response to certain external stimuli. If the latter have such an effect, they are called *signals* or *messages*, and each such message can be assigned a definite amount of information measuring the effect of the message on the system.

Needless to say, every message is carried by some information carrier or channel, and every information gain or loss involves some energy. However, the general theory dealing with information systems is not interested in the physical characteristics of either system or message, not even in the energetic aspect of the transaction: it focuses instead on the net change in the number of final states (or outcomes) of a system affected by a message, whatever its nature. So much so that it regards source, channel and receiver as atomic parts of the system and does not include any physical variables. See Figure A9. (In the popular literature on information it is often stated that an input to a system is called a *signal* iff it elicits an output whose energy is much greater than the input energy. However, information theory does not contain the concept of energy, so the popular characterization is inadequate.)

Consider then a system with n possible final states and a message arriving at the system, the effect of which is to reduce that number of alternatives from n to some number $m \leq n$. The *amount of information* carried by the message is taken to equal $\log_2(n/m)$ bits. (The *bit* is of course the unit of information, i.e. the quantity of information gained by the system when the number of alternatives is halved. In fact, in this case $\log_2(n/(n/2)) = \log_2 2 = 1$.) In short, if a message shrinks the number of final states of a system from n to $m < n$, it is said to carry the quantity of information $I = \log_2 (n/m)$. There need be nothing cognitive, let alone subjective, about this concept of information.

If the signals are random, either because they are generated at random or, more commonly, because the information channel is subject to random disturbances, then the statistical theory of information (Shannon and Weaver, 1949) applies. The basic notion of this theory is that of a random binary physical signal appearing at the receiving end of a communication system. The central postulate of the theory is that the quantity of information of such a signal is $I = \log_2(1/p)$, where p is the probability of the signal's reaching the receiver. If the latter happens to be an intelligent being then I is interpreted as the degree of unexpectedness of the message. But

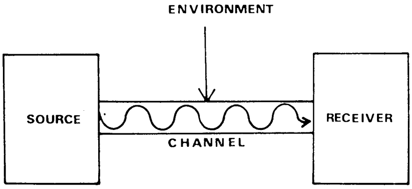


Fig. A9. The components of an information system. The effects of the environment on the channel, when random, are lumped under the category of noise.

this interpretation, legitimate as it is in some applications of statistical information theory to psychology, is irrelevant to communications engineering, molecular biology, and semantics.

One final note of caution. Some claim that information measures organization. The argument runs like this: a deterministic system is predictable, so watching its behavior provides no information; on the other hand a probabilistic system is unpredictable, so whatever it does is surprising or informative. Hence the more disorganized a system the more informative the observation of it. This argument contains several important mistakes. Firstly, the information function is not defined on a set of systems (or of states of a system) but on system-message pairs. Consequently a quantity of information, far from being an intrinsic property of a system (e.g. a transfer RNA molecule), is a mutual property of system and message. Hence it cannot measure the degree of organization of a system nor any other intrinsic property of it. Secondly, systems are neither predictable nor unpredictable: whatever can be predicted can be so with the help of theories and data. The predicate "predictable" is not defined on the set of systems but on the set of pairs ⟨body of knowledge, system⟩. Thirdly, prediction must not be equated with deterministic prediction. If a system is stochastic, as is the case with an atom, a learning organism, or a social group, then its behavior may be predicted statistically – provided we have succeeded in building a true probabilistic theory about it. In this case we may be able to predict probabilities (of e.g. transitions) and a number of properties derived from them, such as averages and standard deviations. Fourthly, a stochastic system – such as a probabilistic automaton – is not chaotic: being probabilistic it is "governed" by probabilistic laws. Thus, though stochastic, an atom is not chaotic like the top of my desk, over which no probability distribution can be defined. (See Vol. 3, Ch. 4, Sec.6.4 for the difference between randomness and chaos.)

In conclusion, information does not measure organization. And there seems to be no better measure, perhaps because organization is an extremely complex property that defies lumping into a single number. What we do have are measures of efficiency, such as thermodynamic efficiency, output/input ratios, or signal/noise ratios. Knowing that a system is highly (or fairly or poorly) efficient we can infer that it is well (or fairly or poorly) organized to attain a certain goal or to help us perform a certain task. But efficiency is an indicator of organization not a measure of it.

APPENDIX B

CHANGE MODELS

In this Appendix the accent will be on change. We shall exhibit both kinematical and dynamical models, first of quantitative, then of qualitative change. And we shall study only extremely general change models, i.e. such that are portable from one field of inquiry to another. As in the case of Appendix A, most of the material to be presented is standard or has at least appeared before. But the interpretation and the philosophical discussion is often novel.

1. KINEMATICAL MODELS

1.1. *Global kinematics*

A kinematical model of a system is a theory representing the change, step by step, in some of the properties of the system. The simplest kinematical model assumes that the properties of the system are representable by smooth functions, and that the collection of all of these, i.e. the state function, is a time dependent function with values in $\mathbb{R}^n$ obeying an equation of evolution of the form

$$\dot{\mathbb{F}} = \mathbb{G}(\mathbb{F}, t).$$

Example The rate of change of the state function is a linear combination of its own components, i.e. $\mathbb{F} = G\cdot\mathbb{F}$, where G is a square matrix with time independent coefficients. The solution is $\mathbb{F}(t) = e^{Gt}\cdot\mathbb{F}(0)$, where $\mathbb{F}(0)$ is the value of the state function at $t = 0$.

Some of the components of $\mathbb{G}$ may remain constant throughout the evolution of the system. In this case they are called the (time) *invariants*, or *constants of the motion*, of the system. (The system as a whole need not move through space.) If all the n components of $\mathbb{G}$ vanish, the system has n constants of motion and is always in a steady state even though its components may not be in such a state.

Another systemic or global property that can be studied with the help of a kinematical model is stability. A system represented by a state equation of the form $\dot{\mathbb{F}} = \mathbb{G}(\mathbb{F}, t)$ is (a) in a *stationary state* (or in *equilibrium*) during a certain time interval iff $\dot{\mathbb{F}} = 0$ during that interval (so that $\mathbb{F}$

equals a constant n-tuple); (*b*) *asymptotically stable* iff $\mathbb{F}$ approaches an equilibrium value for increasing values of t.

Example Suppose a system is characterized by just two properties, represented by F_1 and F_2, so that its equations of evolution are

$$\dot{F}_1 = G_1(F_1, F_2, t), \qquad \dot{F}_2 = G_2(F_1, F_2, t).$$

The equilibrium property can be found by going over to the state space, namely by dividing one equation by the other to obtain

$$\frac{\mathrm{d}F_1}{\mathrm{d}F_2} = \frac{G_1}{G_2},$$

which represents the possible processes in the state space. The system is stable iff $\mathrm{d}F_2/\mathrm{d}F_1$ approaches a definite number as F_1 increases. This number is the slope of a straight line in the state space, namely the equilibrium trajectory. If on the other hand the system diverges from the (imaginary) equilibrium line, it is unstable. See Figure Bl. (The equilibrium trajectory may be a finite segment or just a point.)

1.2. *Analytical Kinematics*

In the preceding subsection we dealt with the global kinematics of an arbitrary system. In contrast, analytical kinematics pays attention to the components of a system and the links among them. Assume, for the sake of simplicity, that a system has just two components characterized by one property each. Call F_1 and F_2 the functions representing the peculiar property of component 1 and component 2 respectively. Suppose that these functions vary smoothly in the course of time and that the law of evolution is

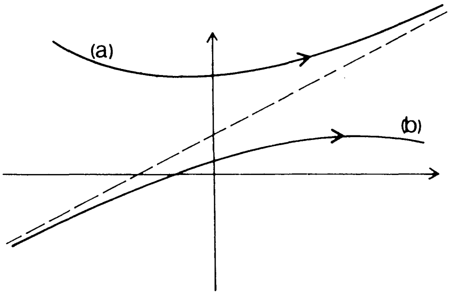

Fig. B1. (*a*) Stable system. (*b*) Unstable system.

$$\dot{\mathbb{F}} = \mathbb{G}(\mathbb{F}) \quad \text{with} \quad \mathbb{F} = \langle F_1, F_2 \rangle, \quad \mathbb{G} = \langle G_1, G_2 \rangle.$$

Assume further that the system is linear, i.e. that

$$\dot{\mathbb{F}} = A \cdot \mathbb{F} \quad \text{with} \quad A = \begin{Vmatrix} a_{11} & a_{12} \\ a_{21} & a_{22} \end{Vmatrix}, \quad \text{where } a_{ii} \in \mathbb{R}.$$

If the off-diagonal coefficients vanish or are very small compared with the diagonal elements, then each component evolves separately or nearly so and, instead of a system proper, we have just an aggregate. Otherwise the evolutions of the system components are coupled.

Example Let $F_i(t)$ represent the amount of stuff of some kind in the ith component of the system at time t. (Such stuff can be matter, information, goods, capital, or what have you.) The system will be in a stable state, and remain in it, provided each component gives back as much stuff as it receives, i.e. iff $a_{12} = a_{21}$. Any departure from this equilibrium state will ensue in an uneven distribution of the stuff measured by F_i – i.e. there will be wind, a leak, an imbalance of payment, a migratory flow, or some other diffusion or transport process. If this trend continues unchecked – i.e. if the system lacks control mechanisms – the entire stuff may end up by concentrating in one of the components. At this point of maximal heterogeneity the exchange may cease and thus the system itself will come to an end *qua* system: each component starts evolving independently from the other. In short, depending on the control mechanisms, whatever disparity there was will either level out (as is the case with heat transfer) or be greatly enhanced (as is the case with unchecked capital transfer). In short, if balance is required then checks are called for.

1.3. *Balance Equations*

So far in this Appendix we have not singled out any state variable representing the transactions of the system with its environment. We shall now remedy this shortcoming. To this end we shall have to introduce the concept of ordinary (physical) space.

Example In $\dot{\mathbb{F}} = \mathbb{G}(x, t)$ set $\mathbb{G} = - \nabla \cdot j$, where j is a vector valued function of position and time representing the flux of something. This law schema occurs so frequently under different guises that it is called the *general balance* (or *conservation* or *continuity*) equation, and is sometimes regarded as a purely mathematical statement without any factual content. Let us examine this matter.

Let σ be a system with volume V and surface S in Euclidean three-space. (We are assuming that σ is not a megasystem, so it does not require Riemannian geometry.) Call ρ an intensive (nonextensive) property of ε, and assume that σ interacts with its environment. By definition, the extensive property ε associated with ρ is

$$\varepsilon(\rho, t) = \int_V dV \rho(\sigma, x, t).$$

For the sake of definiteness think of ρ as the mass density and of ε as the total mass of the system.

We now assume the following factual hypothesis:

POSTULATE B1 For every extensive property ε of a system interacting with its environment, ε may change in the course of time in two (mutually compatible) ways: spontaneously (internally) or as a consequence of system-environment interactions. More precisely, the rate of change of ε is composed of two parts: a source s and a flux j, or

$$\dot{\varepsilon} = \int_V \mathrm{d}V s + \int_S \mathrm{d}S\, j_n,$$

where j_n is the projection of j onto the interior normal to S. See Figure B2.

Using now Green's theorem, a purely mathematical result, we derive

THEOREM B1 If ρ is the intensive property associated with the extensive property ε occurring in Postulate B1, then

$$\dot{\rho} + \nabla \cdot j = s.$$

This is the local (rather than integral or global) balance equation. It is not a special law statement but a *law schema*: it holds for every intensive

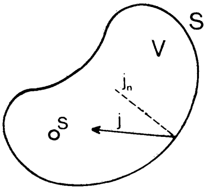

Fig. B2. Transactions of a system with its environment as reflected in the rate of change of the former's extensive property ε. This rate consists of the (positive or negative) contribution of the source (or sink s) and the (positive or negative) contribution of the flow j.

property of an arbitrary system, ergo it will occur as often as intensive properties are treated, whether in quantum mechanics or in continuous models of traffic flow. (The only limitation on it is that it is local, i.e. it holds only in the neighborhood of a reference frame.)

Example Let $j = -a(\partial\rho/\partial x) - b\rho$, with a and b real numbers, and $s = 0$. Then

$$\dot{\rho} = a\,\partial^2\rho/\partial x^2 + b\,\partial\rho/\partial x$$

represents the superposition of a diffusion process, that may be random, and a drift caused by the force $b\,\partial\rho/\partial x$. But even this is just a law schema unless ρ is interpreted in factual terms.

Theorem B1 allows us to give a quantitative definition of the notion of system closure:

DEFINITION B1 Let a system σ interacting with its environment possess n intensive properties ρ_i with the corresponding fluxes j_i, where $1 \leq i \leq n$. Then σ is *isolated* from (*closed* to) its environment during a given time interval

(i) *in the ith respect* iff the flux j_i vanishes on the system boundary for all time in the given interval;

(ii) *in all respects* iff all the fluxes j_i vanish on the system boundary for all time in the given interval.

COROLLARY B1 For any system isolated (closed) in the ith respect, $\dot{\rho}_i = s$.

Moral: Before blaming any changes in the system on its environment, search for the system's internal sources of change. This holds not only in the natural sciences but also in the social ones.

1.4. *Lagrangian Framework*

Consider a system of any kind with n components each of which is characterized by just three basic state functions (called *generalized coordinates*), the values of which depend only on a phase variable interpretable as the time coordinate of a certain reference frame. A Lagrangian model of such a system boils down to a certain function L of the $3n$ generalized coordinates, their rates, and time, that satisfies a certain extremality condition. Because the nature of the components is left unspecified, the model fits any system with a finite number of distinct parts, be it physical, biological, or social. This referential generality explains the wide use of lagrangian kinematics in a variety of scientific and technological fields.

A possible formalization of the notion of a lagrangian model is given by

DEFINITION B2 Let σ be a system composed of n parts and moreover one with a constant composition, i.e. such that $\mathscr{C}_t(\sigma) = \mathscr{C}_{t'}(\sigma)$ for any t, $t' \in T$. Then the structure $\mathscr{L} = \langle T, Q, L \rangle$ is a *lagrangian model* of σ iff

(i) T is a subset of the real line ordered by the relation $\leq$ of temporal priority or simultaneity, and every $t \in T$ represents an instant of time;

(ii) $Q = \{q_i \mid q_i\colon T \to \mathbb{R} \;\&\; 1 \leq i \leq 3n\}$ is a set of time dependent, real valued and once differentiable functions [the basic state functions of the system];

(iii) the $6n$-tuple $\langle q_1(\sigma, t), \ldots, q_{3n}(\sigma, t), \dot{q}_1(\sigma, t), \ldots, \dot{q}_{3n}(\sigma, t) \rangle$ represents the state of σ at time t;

(iv) L is a real valued function of the state variables, their rates, and t – i.e. $\langle q_i(t), \dot{q}_i(t), t \rangle \mapsto L(q_i, \dot{q}_i, t)$ – such that, for any $t \in [t_1, t_2] \subset T$ and fixed end points $q_i(t_1)$ and $q\,(t_2)$, the integral

$$I =_{df} \int_{t_1}^{t_2} \mathrm{d}t\, L\,(\sigma, q_i, \dot{q}_i, t)$$

is either minimal or maximal.

By performing the indicated first order variations (i.e. by computing δI and setting it equal to 0) it is easily seen that the above axiomatic definition entails the following system of $3n$ equations

$$\frac{\mathrm{d}}{\mathrm{d}t}\frac{\partial L}{\partial \dot{q}_i} - \frac{\partial L}{\partial q_i} = 0, \quad 1 \leq i \leq 3n.$$

If there are constraints, i.e. if the generalized coordinates q are not mutually independent, the equations of "motion" are more general: the right hand side equals a function Q_i representing the net effect of the constraints.

Sometimes these kinematical equations can be assigned a dynamical interpretation, namely as representing a balance of forces. In particular $\partial L/\partial q_i$ represents the intensity of the combined action of the environment and the rest of the system upon the component characterized by three values of the index i, and Q_i the forces amounting to the constraints. The latter are particularly important in the case of social systems, where no variable can be said to be independent of the others.

Note that so far we have not specified the Lagrangian function L. A suitable choice of L and of the semantic assumptions concerning the generalized coordinates q_i will yield the laws of particle mechanics. An alternative interpretation yields the theory of electrical networks. Still another interpretation ensues in a certain theory of population dynamics – and so on. In sum, the lagrangian formalism is subject-matter independent. For this reason it belongs not only to science and technology but also to ontology (Bunge, 1974c).

In many fields of inquiry the equations of evolution are of the form

$$\dot{\mathbb{F}} = \mathbb{G}(\mathbb{F}, t)$$

(Sec. 1.1). These equations are just a particular case of the lagrangian formalism with constraints. In fact regarding the components F_i of the state function $\mathbb{F}$ as the generalized coordinates, and introducing the definitions

$$L =_{df} \sum_{k=1}^{n} F_k \dot{F}^k - \sum_{k=1}^{n} G_k F^k$$

$$Q_i =_{df} \mathbb{F} \cdot \frac{\partial \mathbb{G}}{\partial F_i},$$

the two sets of equations coincide. (And, because $\partial L/\partial \dot{F}_i = F_i$, the generalized momenta $p_i = \partial L/\partial \dot{F}_i$ are seen to coincide with the corresponding generalized coordinates. This does no harm since, in general, the generalized coordinates are not interpretable as position coordinates. Thus in the case of a society F_1 may represent the population, F_2 the energy consumption per capita, F_3 the GNP per capita, and so on.) So much for the Lagrangian models of discrete systems.

In the case of a continuous system, such as an elastic body, an electric field, or a sufficiently dense population of organisms, one starts from a lagrangian density and obtains L as the volume integral of that density. As with the discrete case, a few rather mild conditions on the Lagrangian suffice to yield a theory schema with a wide coverage – so wide indeed that, when enriched with suitable subsidiary conditions or hypotheses, it yields every one of the classical field theories (Edelen, 1962). Such conditions specify then a specific Lagrangian model.

What is usually called *axiomatic field theory* intends to discharge a similar function with respect to the quantum field theories, in particular quantum electrodynamics. However, unlike the general classical field theory mentioned a moment ago, its quantum counterpart does not yield quantum electrodynamics as a special case. "It can at most give a framework for a concrete theory of existing particles and their corresponding fields" (Jost, 1965, p. xi). In addition, one hopes that this approach may avoid the inconsistencies that mar the quantum field theories. Its role in metaphysics is yet to be investigated.

We close this subsection with an historical remark. The Lagrangian framework was foreshadowed by Maupertuis as a synthesis of dynamics and metaphysics. It was brought to fruition by Lagrange, who freed it from metaphysics, and it was generalized beyond dynamics by Maxwell. The axiom contained in Definition B2 (iv) is one of the most secure and yet misinterpreted principles of science. Maupertuis took the (action) integral I to be always a minimum and interpreted this as a sure sign of divine wisdom: Nature always chose the paths that minimized I. It was later discovered that in some cases (notably in optics) I is not a minimum but a maximum, so the principle was rechristened from that of minimal to that of extremal action. Nevertheless a number of physicists, among them Planck and Margenau, continued to regard Maupertuis' principle as an expression of purpose and design. This is mistaken if only because the principle, together with some lemmas borrowed from the variational calculus, entails the equations of motion – in which no traces of purpose or design have ever been detected. It is not that the system behaves in order to minimize or maximize its action: it is just a law, and an extremely pervasive one, that all systems behave that way. Because of this generality the Lagrangian framework should be recognized as belonging to the intersection of science and metaphysics.

1.5. *Kinematical Analogy*

We close this section with some remarks on the notion of kinematical analogy. Any systems which, regardless of their detailed composition and structure, have the same kinematics – hence are described adequately by the same equations of evolution – can be said to be *kinematically analogous* (or *equivalent*). For example some periodic oscillations, whether mechanical, electrical, chemical, biological, or economic, happen to satisfy the same differential equations, hence they are kinematically analogous. Thus the relaxation oscillations in a vacuum tube amplifier are described by the equation $\ddot{x} - a(1 - x^2)\dot{x} + bx = 0$, which has been said to describe also the noise made by scratching a piece of chalk on a blackboard, the waving of a flag in the wind, shivering from cold, and the periodic recurrence of epidemics.

There can be no doubt that the finding of kinematical analogies can play a heuristic role and save time. But they have hardly any ontological import except insofar as they show that different mechanisms may result in similar overall behavior patterns, whence the study of behavior does not exhaust that of reality. For example brownian particles, domestic flies, and drunkards move randomly, but the underlying mechanisms are very different, so that the observation that all three are kinematically analogous has no metaphysical significance. What does have ontological import is the finding of *dynamical* analogies among systems of different kinds, i.e. the discovery that certain *mechanisms* – such as transport, diffusion, merging, cooperation, competition, random shuffling, and casual mutation – are conspicuous on all levels. So, let us turn our attention to mechanisms.

2. DYNAMICAL MODELS

2.1. *Generalities*

A dynamical model of a system is a kinematical model (Sec. 1) some variables of which are interpretable as "driving" others. In other words, a dynamical model involves a change *mechanism*, i.e. either a subsytem or a process whereby the changes in some properties of the system effect changes in some other properties of the same system. Morever all such changes are spatiotemporal or reducible to changes in time (such as rates) or in space (such as gradients).

Example 1 The geographic distribution of a biospecies can be explained as the outcome of the action of three separate mechanisms: random diffusion, drift, and environmental resistance (or selection pressure). A dynamical model of the spatial pattern of a species (or rather a family of populations of the given species) is this. The rate of change of the population density ρ of the given collection of populations at some point x on the surface of the planet is

$$\frac{\partial \rho}{\partial t} = \underset{\text{Diffusion}}{\alpha\, \partial^2\rho/\partial x^2} - \underset{\text{Drift}}{2\beta\, \partial\rho/\partial x} + \underset{\substack{\text{Environmental}\\ \text{pressure}}}{\gamma\rho(\rho - 1)}.$$

Example 2 Much the same holds if ρ is interpreted, not as the actual population density, but as the probability density, so that $\rho\, \mathrm{d}S$ represents the probability that $\rho\, \mathrm{d}S$ individuals live in the area $\mathrm{d}S$. In this case all three forces are stochastic, like the pushes exerted by molecules on a brownian particle. *Example 3* Field models are a kind of dynamical model. A field is a thing spread in a continuous manner over an expanse of space. (Think of the gravitational or of the magnetic field of our planet.) In principle a field does not qualify as a system any more than a particle does, for neither has atomic parts. However, a collection of fields superposed in a given region of space does qualify as a system. An electromagnetic wave is an example of a pure field system. Also, a field may play a part in a system not made up exclusively of fields: its role is that of glue that keeps the nonfield components together. We call a *field theoretic model* of a system any model in which field concepts occur essentially, as is the case with the (theoretical) model of a molecule. The "fields" invented by some biologists, psychologists, and social scientists, are phoney, for they are not substantial continua and are not described by field equations: they are just metaphors.

A field theoretic model is mechanismic, not phenomenological, but its mechanism is nonmechanical. (Mechanical mechanisms are a proper subset of mechanisms.)

2.2. *Formalities*

We repeat in a slightly more exact way the definition of a mechanism given at the beginning of the last subsection:

DEFINITION B3 Let σ be a system. Then a *mechanism* of σ is either
(i) a component m of σ such that m acts in σ, or
(ii) a process m in σ such that other processes in σ depend upon m.

And now we assume

POSTULATE B2 Every system has some mechanism.

Clearly this postulate (*a*) overreaches experience, (*b*) goes against the grain of phenomenalism and descriptivism (e.g. behaviorism), and (*c*) encourages theorizing. The kind of theorizing our postulate stimulates is, of course, the building of dynamical models. A *dynamical model* of a system may be defined as a model representing one or more mechanisms of the system.

A standard formulation of a dynamical model is within the general framework of hamiltonian dynamics. Just as every kinematical model can be formulated in Lagrangian terms (Sec. 1.4), so nearly every dynamical model can be formulated in a Hamiltonian fashion. It will be recalled that the former has just one set of $3n$ basic state functions, namely the generalized coordinates q_i. A Hamiltonian model, on the other hand, rests on two sets of basic state functions: the very same generalized coordinates q_i and the corresponding generalized momenta p_i, which are logically independent of the former. Just as the solutions q_i of a Lagrangian problem may represent the spatial configuration of the system, so the corresponding p_i represent the dynamics of the system. In particular, the rates $\dot{p}_i$ may represent the forces acting on the various parts of the system. If the Lagrangian L of the system is known, then the p_i are given by $p_i = \partial L/\partial\dot{q}_i$, and the hamiltonian of the system by $H = \Sigma p_i\dot{q}_i - L$. But if L is unknown then the problem must be formulated afresh by conveniently choosing the basic variables and guessing the adequate Hamiltonian. The basic equations of motion are

$$\dot{p}_i = -\partial H/\partial q_i, \qquad \dot{q}_i = \partial H/\partial p_i.$$

So, the solution of a hamiltonian problem is compressed into the state function $\mathbb{F} = \langle q_1, q_2, \ldots, q_{3n}, p_1, p_2, \ldots, p_{3n}\rangle$. Every value of this function represents a possible state of the system. And as time goes by the tip of $\mathbb{F}$ traces a trajectory in the state space of the system, which in this case is called its *phase space.*

Although the general hamiltonian theory – namely that in which H is left unspecified and the basic state variables uninterpreted – belongs to scientific ontology, we shall not go into any details of it. (For this and a few other general dynamical theories, see Bunge, 1967b, Ch. 2.) Our purposes in mentioning the theory here are (*a*) to emphasize the richness of the ontology that originates in science, and (*b*) to elucidate the concept of dynamical analogy. The latter may be defined as follows. Let σ and σ' be two systems modeled by the Hamiltonians $H_\sigma(q, p, t)$ and $H_{\sigma'}(q', p', t')$ respectively. Then σ and σ' are said to be *dynamically* analogous iff H_σ and $H_{\sigma'}$ are formally the same up to a similarity transformation of its dependent variables – i.e. if $q' = aq$, $p' = bp$, and $t' = ct$, where a, b and c are complex numbers. Nothing is required of the interpretation of these variables.

Let us next discuss the dynamics of processes of two special yet rather widespread kinds, namely competition and cooperation, which will be treated jointly in a single dynamical model.

2.3. *The Pervasiveness of Cooperation and Competition*

When two or more things get together and form a system, they may be said to cooperate with one another even if they do not do so deliberately.

For example, each of the syntheses (physical, chemical, biological, or social) $A + B \rightharpoonup C$ and $A + D \rightharpoonup E$ may be regarded as a cooperative process: the A's cooperate with the B's to form C's, and likewise for the second reaction. However, if the two processes occur simultaneously at the same place, then the two cooperative processes compete with each other: indeed, in this case the B's and the D's compete for the A's. So, in this case there is both cooperation (in some respects) and competition (in others). Likewise two families (or other sociosystems) may compete with one another while cooperating internally.

A possible definition of the notions of interest is this:

DEFINITION B4 Let x, y and z be things. Then

(i) x *cooperates* with y iff there is a system z such that x and y are in the composition of z;

(ii) x *competes* with y for z iff the formation of a system composed of x and z interferes with that of a system composed of y and z.

Note that, according to this definition, competition is not the opposite of cooperation. Moreover two things may cooperate in certain respects and compete in others.

Cooperation has received far less attention than competition. In particular, most philosophers since Heraclitus have stressed war at the expense of cooperation, ignoring that intersystemic competition calls for intrasystemic cooperation. On the other hand biologists, pharmacologists and physicians are fond of emphasizing that the components of the normal cell act in cooperation, that every healthy organism is synergic, and that only sickness and senility cut the cooperative ties.

Of late physicists have joined life scientists in studying a number of cooperative processes. One striking discovery along this line marked the birth of a whole new branch of science, namely plasma physics. Collective or molar modes of oscillation and propagation were discovered in such lowly systems as bodies constituted by very hot and highly ionized gases – which, according to classical ideas, should be the paradigm of chaos and homogeneity. Plasma waves, both stationary and traveling, as well as the emergence of complex shapes of plasma bodies (plasmons), gave the lie to the belief that in every gas all a molecule can do is to move haphazardly and collide with other molecules in a random fashion without ever giving rise to a new system characterized by novel overall modes of behavior. At about the same time chemists discovered the hydrogen bond, which can give rise to marvels of cooperation such as the biomolecules. In short, cooperation is nowadays just as "in" as competition was one century ago. Which is just as well, for unless cooperation is acknowledged alongside competition, the very existence of systems cannot be accounted for. For one thing the pervasiveness of assembly processes would not have been recognized if scientists had adhered to the Heraclitean ontology of strife.

We shall stick our neck out and assume

POSTULATE B3 Cooperation is about as frequent as competition.

We shall presently atone for the vagueness of this formulation by reviewing a mathematical model of processes wherein cooperation intertwines with competition (Bunge, 1976).

2.4. *The Dynamics of Competitive–Cooperative Processes*

Suppose that two things or systems, *a* and *b*, consume or produce a third thing *c*. We make no assumption concerning the nature of these things, let alone the mechanism of consumption or production. But we do assume something about the modes of cooperation and competition between *a* and *b* with regard to *c*. In fact we assume that each component, when on its own, consumes or produces *c* at a constant rate (possibly nil), and that each may or may not succeed in making ends meet. We also assume that the components are sure to attain the optimum level (of consumption or of production) if they cooperate with one another. Finally, we suppose that this cooperation becomes intenser the more it is needed, that it ceases when no longer needed, and that from then onwards it turns into hindrance, so that growth remains under control. Such a process can be formalized as follows.

Let $A(t)$ and $B(t)$ be the instantaneous amounts of thing *c* consumed or produced by the components *a* and *b* respectively, and call α and β the optimum or satiety levels. Further, let

$$A(0) = c_1 < \alpha, \qquad B(0) = c_2 < \beta$$

be the initial values. In the absence of interaction the rates are assumed to be constant (possibly zero):

$$\dot{A} = a_{11}, \qquad \dot{B} = a_{22} \quad \text{with} \quad a_{11}, a_{22} \in \mathbb{R}^{+}.$$

If these rates are nil, no processes occur. If they are positive, each individual eventually attains and surpasses its optimum level. Furthermore if cooperation sets in from the start, *a* will help *b* in proportion to the latter's needs, i.e. in such a way that the imbalance $\beta - B$ will be offset; and b in turn contributes in proportion to the imbalance $\alpha - A$, though not necessarily with the same intensity. This mutual help, we have assumed, is positive as long as there is a deficit (negative balance); it becomes nil on attaining satiety, and negative as soon as there is superavit (positive balance). The simplest formulas representing such a cooperative process are the nonlinear equations

$$\dot{A} = a_{11} + a_{12}(\alpha - A)B, \qquad \dot{B} = a_{22} + a_{21}(\beta - B)A$$

with $a_{ij} \geq 0$ for $i, j = 1, 2$.

The coefficient a_{12} measures the strength of the help a gets from b, while a_{21} measures the intensity of the help a lends b. At the optimum point $\langle \alpha, \beta \rangle$ there is neither help nor hindrance: each component fends for itself, so the system breaks down momentarily.

We spare the reader the treatment of the general case in the vicinity of the optimum point, showing that, in effect, no sooner does a attain the α level than its partner b turns against it forcing it to slow down its rate of consumption or of production. (Cf. Bunge, 1976.) Instead, we shall study the particular case when the two partners behave in exactly the same way. In this case, i.e. for $c_1 = c_2 = c$ (no initial advantage), $a_{11} = a_{22}$ (same individual rates), $a_{12} = a_{21}$ (symmetric help) and $\alpha = \beta$ (same requirements), we are left with a single equation of evolution, namely

$$\dot{X} = a_{11} + a_{12}(\alpha - X)X, \qquad X = A, B.$$

The general solution to this equation is found to be

$$X(t) = a_{11}t + \frac{\alpha c}{c + (\alpha - c)\exp(-a_{12}\alpha t)}.$$

If each partner is self-sufficient ($a_{11} = a_{22} > 0$), cooperation only speeds up the process up to the optimum point, and curbs it after that point. Otherwise (i.e. if $a_{11} = a_{22} = 0$), mutual help makes the process possible. Indeed, the second term of the last equation represents the growth of A (which is equal to B) from the initial value c towards the asymptote $A(\infty) = \alpha > c$. Rivalry from this point on prevents unlimited growth in either consumption or production. See Figure B3. This limitation takes place whether or not there is an external limitation such as scarcity of resources: the control is strictly internal. Not that there are no external limitations; only, our model does not take them into account.

General dynamical models of this kind have at least three possible uses:

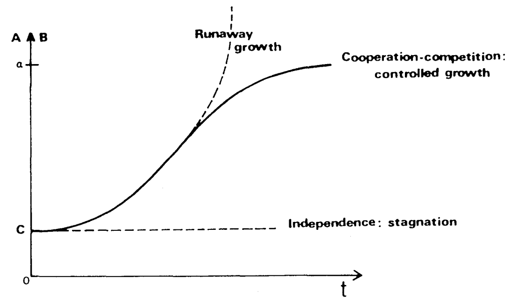

Fig. B3. Full line of a system composed of partners that cooperate and compete ($a_{12} \neq 0$) but are powerless in isolation (i.e. when $a_{11} = a_{22} = 0$). Dotted line: stagnation in the absence of interaction (i.e. when $a_{12} = 0$).

(*a*) they may suggest the search for real systems (e.g. in morphogenesis, neurology, ecology, or sociology) that approach a zero growth state in some variable as a result of their cooperative-competitive structure; (*b*) they may stimulate the building of specific theories covering real systems behaving in the way outlined by the model; (*c*) they may help in planning social controls. In particular, our model suggests redesigning society in such a way that each member helps his/her neighbor in proportion to his/her own ability and the other party's needs, and also controls his/her partner's growth and is in turn controlled by it, thus preventing scarcity as well as waste, and thus combining the good features of competition with those of cooperation.

3. QUALITATIVE CHANGE MODELS

3.1. *Kinematical: Birth and Death Operators*

All sciences deal with qualitative changes and even deep ones such as changes in kind, or transmutations of things of one kind into things of another. Such changes in kind can be conceptualized in several ways. The simplest is by treating each kind as a graph node, and the transformation as a graph edge, of a directed graph. The latter is then a directed and connected graph – e.g. one representing a lineage such as a disintegration schema or a phylogenetic tree. If a quantitative, yet still purely phenomenological, representation of such qualitative changes is wanted, then one has to devise a way of saying how many things of each kind emerge or disappear in a given process, without suggesting any transmutation mechanisms. We shall exhibit one such model, inspired in quantum field theory.

Consider a system composed of things of different species (natural kinds) K_m, where m is a natural number greater than 2. Call n_m the instantaneous population of kind K_m in the system. The state of the system such that there are n_1 things of kind K_1, n_2 of kind K_2, and in general n_m of kind K_m, can be represented by a state function $u(n_1 n_2 \ldots n_i \ldots)$. Thus

$u(0000\ldots)$ represents the no-system state,

$u(1000\ldots)$ represents the state such that the system has a single component of kind K_1 and none of the others;

$u(0n0\ldots)$ represents the state of the system when it is composed of n units of kind K_2.

We assume that the totality of such state function values spans the state space S of the system. Moreover we postulate that S is a vector space, so that every linear combination of u's represents a possible state of the system. The unit vectors $\varepsilon_1 = (100\ldots)$, $\varepsilon_2 = (0100\ldots)$, $\varepsilon_3 = (00100\ldots)$ constitute a basis of the vector space.

We now introduce the *birth operators* $B_i \colon S \to S$ defined by

$$B_i u(n_1 \ldots n_i \ldots) = (n_i + 1)^{1/2} \, u(n_1 \ldots n_i + 1 \ldots).$$

B_i represents the change of state of the system brought about by the increase by one thing of kind K_i in the composition of the system.

Similarly we define the disappearance of one unit of kind K_i from the composition of the system:

$$D_i u(n_1 \ldots n_i \ldots) = (n_i)^{1/2} \, u(n_1 \ldots n_i - 1 \ldots),$$

and call $D_i \colon S \to S$ the *destruction operator* of kind K_i. It can be shown (e.g. Mandl, 1959) that the two operators are mutually adjoint, i.e. $D_i = B_i^\dagger$, where the dagger designates transposition and conjugation of the entries in the matrix representations of the operators. It follows that $B_i \, D_i$ leaves things in the state they were to begin with, i.e.

$$B_i D_i u(n_1 \ldots n_i \ldots) = n_i u(n_1 \ldots n_i \ldots).$$

The eigenvalues of $B_i D_i = B_i B_i^\dagger$ are the possible populations of kind K_i in the system. Therefore $B_i D_i = N_i$ is an operator that can be interpreted as the population (or occupation number) operator for the kind K_i.

The basic birth operators can be combined to yield operators representing arbitrary changes in the composition of the system. Thus $(B_i^\dagger)^p B_j{}^q$

represents the destruction of p individuals of kind K_i and the birth of q individuals of kind K_j. In other words,

$$(B_i^{\dagger})^p B_j^q \text{ represents the reaction } pK_i \longrightarrow qK_j,$$

whereas $(B_j^{\dagger})^p B_i^q$ represents the converse reaction. Mathematically speaking, $(B_i^{\dagger})^p B_j^q$ transforms the vector $u(n_1 \ldots n_i \ldots n_j \ldots)$ into $(n_i!(n_i + q)!/p!n_j!)^{1/2}$ $u(n_1 \ldots n_i - p \ldots n_j + q \ldots)$. Finally, the combinations of birth operators generate the entire state space out of the no-system (or zero) state $u(000\ldots)$ Thus $B_i^p B_j^q u(000\ldots)$ is proportional to the state vector representing the situation where there are p components of kind K_i and q of kind K_j in the system, and nothing else.

Because we have made no assumption other than that the changes under consideration are discrete changes in kind, the above is a framework for a kinematical (phenomenological) theory rather than a theory proper. But this is what we want in ontology: a more specific formalism would belong in science.

3.2. *Dynamical: Random Hits*

We shall presently sketch an extremely simple theory, both dynamical and stochastic, suggestive of a very general ontological hypothesis. The theory deals with the mutagenic effect of external agents impinging randomly upon a system. (See Maynard Smith (1968)). Suppose a system contains m components (*targets*) sensitive to certain discrete transmuting agents (*bullets*). The sensitive components must be a critical part of the whole thing even if they are only a small part: they may be atomic or cellular nuclei, organelles, key sociosystems, or what not. The disrupting agents can be ionizing particles, radiations, terrorists, bureaucrats, or what have you. Every hit or collision of a bullet with a target is assumed to either mutate or destroy the latter and, in any case, to effect a change in kind. The problem is to compute the probability that n random bullets will produce a change in kind (or transmutation) in a system with m sensitive components.

Assume that each bullet can act on a single target rather than being able to kill several birds at one stroke: i.e. let us restrict our attention to single hits. Call p the probability that an arbitrary bullet will mutate a target, and suppose that a total of n bullets fire at the system in an aimless and unconcerted way. Suppose also that the effect each successful bullet produces has no consequences on the other targets of the system – i.e. that the effects are mutually independent, so that only their cumulative effect is of interest. Since the probability that a bullet fails to hit a target is $q = 1 - p$, the probability that the target will fail to mutate under the action of n random bullets is

$$q^n = (1 - p)^n \cong e^{-pn} \quad \text{for large } n.$$

And the probability that all m sensitive components will remain unaltered after a round of n firings will be the m-fold product of the above, i.e.

$$Q \cong (e^{-pn})^m.$$

Consequently the probability that all m sensitive components will be hit and mutate is

$$P = 1 - Q \cong 1 - e^{-pmn},$$

which approaches 1 as the number of bullets increases. Therefore the average number of mutations induced by the n bullets is Pm, which approaches m with increasing n. In words: the probability that the bullets be ineffectual decreases exponentially as the number of bullets increases, while the probability that the system undergoes a radical transmutation increases monotonically with the number of bullets: see Figure B4.

Now, every system is subjected to some mutagenic agent or other – fast charged particles, slow neutrons, hard radiation, predators, critics, saboteurs, or what have you. Moreover, whether the missiles are aimed and concerted, or random, they are likely to have some effects – not necessarily destructive but in any case transmuting. Therefore we can make the sweeping generalization

POSTULATE B4 Every system except the world is subject to random actions that eventually elicit its breakdown or its mutation (change in kind).

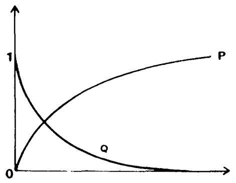

Fig. B4. Probable effects of random hits.

Note that we are not assuming that all mutagenic agents are external to the system concerned: it suffices that they be external to its sensitive components. For example, chromosomes are subjected not only to external radiation but also to thermal and chemical actions of the surrounding protoplasm. And every cultural system is the beneficiary or victim not only of economic and political actions but also of its own creative and destructive members.

GENERAL PREFACE TO THE *TREATISE*

This volume is part of a comprehensive *Treatise on Basic Philosophy*. The treatise encompasses what the author takes to be the nucleus of contemporary philosophy, namely semantics (theories of meaning and truth), epistemology (theories of knowledge), metaphysics (general theories of the world), and ethics (theories of value and of right action).

Social philosophy, political philosophy, legal philosophy, the philosophy of education, aesthetics, the philosophy of religion and other branches of philosophy have been excluded from the above *quadrivium* either because they have been absorbed by the sciences of man or because they may be regarded as applications of both fundamental philosophy and logic. Nor has logic been included in the *Treatise* although it is as much a part of philosophy as it is of mathematics. The reason for this exclusion is that logic has become a subject so technical that only mathematicians can hope to make original contributions to it. We have just borrowed whatever logic we use.

The philosophy expounded in the *Treatise* is systematic and, to some extent, also exact and scientific. That is, the philosophical theories formulated in these volumes are (*a*) formulated in certain exact (mathematical) languages and (*b*) hoped to be consistent with contemporary science.

Now a word of apology for attempting to build a system of basic philosophy. As we are supposed to live in the age of analysis, it may well be wondered whether there is any room left, except in the cemeteries of ideas, for philosophical syntheses. The author's opinion is that analysis, though necessary, is insufficient—except of course for destruction. The ultimate goal of theoretical research, be it in philosophy, science, or mathematics, is the construction of systems, i.e. theories. Moreover these theories should be articulated into systems rather than being disjoint, let alone mutually at odds.

Once we have got a system we may proceed to taking it apart. First the tree, then the sawdust. And having attained the sawdust stage we should move on to the next, namely the building of further systems. And this for three reasons: because the world itself is systemic, because no idea can

become fully clear unless it is embedded in some system or other, and because sawdust philosophy is rather boring.

The author dedicates this work to his philosophy teacher

Kanenas T. Pota

in gratitude for his advice: "Do your own thing. Your reward will be doing it, your punishment having done it".

PREFACE TO *EPISTEMOLOGY I & II*

We have learned a good deal about many things, we have come to realize that if we value knowledge we should continue to inquire because we shall never know enough, and we keep expanding, applying, and diffusing nearly every bit of knowledge we manage to acquire. So many people are engaged in generating new knowledge, using it, and diffusing it, that economists speak of the *knowledge industry.*

Yet we are still remarkably ignorant about knowledge itself. We still argue whether it is the brain or the mind that knows, and are uncertain about the cognitive abilities of subhuman animals as well as of computers. We have only the most rudimentary information about the development (ontogeny) and evolution (phylogeny) of such abilities, and we continue to ask whether the study of knowledge is a harmless armchair specialty or a useful cross-disciplinary field of inquiry, both factual and theoretical, scientific and philosophical. In short, while the knowledge industry is thriving, the science and philosophy of knowledge are still in bud.

There are several possible explanations for the underdevelopment of our knowledge of knowledge. One could be that epistemology is impossible: this is the view of the radical skeptics and a few others (e.g. Nelson, 1912). Another view is that epistemology and, in general, philosophy has nothing new left to say (e.g. Rorty, 1979).

I find such skepticism and pessimism unacceptable, in view of the rapidly expanding body of interesting epistemological problems raised by science, technology, and the humanities, as well as recent advances in the physiology, psychology, and sociology of perception, learning, and ideation. There must be an alternative explanation for the underdevelopment of epistemology. We may have to blame the conservatism of most philosophers, who stick to the same old problems and rely exclusively on ordinary knowledge as well as on the authority of classical *isms* instead of engaging in a scientific investigation of the problems of cognition and knowledge. If this is the case, then what epistemology needs is not more obituaries but a radical reorientation. I hope this work will contribute to such renewal. This book and its companion, namely Volume 6 of my *Treatise*, concern the basic traits of cognition and knowledge, as well as the basic principles guiding the acquisition, analysis and utilization of knowledge. Their joint title could well be *Principles of Inquiry*, or *An Inquiry into Inquiry.*

This volume is devoted to general epistemology and methodology; the next, to some epistemological and methodological problems arising in contemporary science and technology. Epistemology, or the theory of knowledge (Fr. *gnoséologie*, Ger. *Erkenntnistheorie*), is the field of research concerned with human knowledge in general—ordinary and scientific, intuitive and formal, pure and action-oriented. And methodology—not to be mistaken for methodics, or a set of methods or techniques—is the discipline that studies the principles of successful inquiry, whether in ordinary life, science, technology, or the humanities.

In this work epistemology is conceived as a merger of philosophy, psychology, and sociology: it describes and analyzes the various facets of human cognitive processes, whether successful or not, and whether or not they bear on everyday matters. Methodology too is descriptive and analytical, but in addition it is prescriptive or normative: it attempts to find out not only how people actually get to know but also how they ought to proceed in order to attain their cognitive goals. Thus both the epistemologist and the methodologist are supposed to describe and analyze experiment, but the methodologist is primarily interested in well designed experiment. In short, whereas epistemology is concerned with inquiry in general, the task of methodology is to find or perfect optimal inquiry strategies.

Yet, for all their differences, epistemology and methodology overlap considerably. Both deal with cognitive processes, so both deserve being called 'epistemology'. After all, it is the same people who succeed and fail in attempting to learn. Both studies should be pursued, and often at the same time, if we are to improve our understanding of the mechanisms of our successes and failures in our cognitive ventures. Fortunately, the two lines of inquiry into inquiry intertwine in the research of a new breed of cognitive psychologists. (See Nisbett and Ross, 1980.)

This book continues an old tradition or, rather, a whole fan of traditions started in ancient Greece and India. But at the same time this work departs from tradition with regard to method. It is hoped that our inquiry into inquiry will be closer to the cognitive sciences and, in general, closer to contemporary research, than to obsolete dogma. More particularly, we shall proceed as follows. We shall pick up the rich legacy of epistemological problems and hints (often optimistically called 'theories') bequeathed to us by the epistemological tradition. We shall enrich it with some of the problems and findings of contemporary scientific, technological and humanistic research, topping it with new hypotheses compatible with the science of the day—in particular neuroscience, psychology, and social science. And we shall elaborate and systematize the whole with the help of a few modest tools such as the concepts of set and function. However, in contradistinction with the former volumes in this *Treatise*, here we shall adopt a far more modest level of formalization. The result is a greater intelligibility—and length. (The formalizations have been put in parentheses and in the Appendices.)

Finally, we shall try and put our epistemological principles to the test: we shall check whether they account for the actual conduct of inquiry or whether they might help improve it. In other words, we want empirical confirmation for our epistemology, and we want it to be useful to research. And, far from confining our considerations to the physical sciences and technologies, we shall take all the sciences and technologies as our testing ground. This undertaking should prove far more rewarding, though also far harder, than writing obituaries of epistemology in the manner of Wittgenstein or Heidegger.

ACKNOWLEDGMENTS

I am grateful to the 25 generations of students in Argentina, Uruguay, the U.S.A., West Germany, Switzerland, México, and Canada, who took my courses in epistemology and methodology, and asked interesting questions or provided valuable information. I also thank the following persons for their advice, criticism, or encouragement: Joseph Agassi (Philosophy, Tel-Aviv University), Antonio M. Battro (Centro de Investigaciones Filosóficas, Buenos Aires), Hervé Barreau (Fondements des Sciences, Université Louis Pasteur, Strasbourg), Félix Córdoba Alva (Centro de Investigaciones Biológicas, La Paz, BCS, México), Mike Dillinger (Linguistics, McGill), Bernard Dubrovsky (Psychiatry, Physiology and Psychology, McGill), José Ferrater Mora (Philosophy, Bryn Mawr College), Manuel Garrido (Philosophy, Universidad Autónoma de Madrid), Alberto Hidalgo (Philosophy, Universidad de Oviedo), Rolfe Leary (Forest Experiment Station, St. Paul, Min.), James McGilvray (Philosophy, McGill), Claude Panaccio (Philosophy, Université du Québec à Trois Rivières), Michel Paradis (Linguistics, McGill), Rafael Pérez Pascual (Physics, UNAM, México), Miguel A. Quintanilla (Philosophy, Universidad de Salamanca), Osvaldo A. Reig (Estudios Ambientales, Universidad Simón Bolívar, Caracas), Marcel Roche (Estudio de la Ciencia, IVIC, Caracas), William R. Shea (Philosophy, McGill), Jane Stewart (Psychology, Concordia University, Montréal), José Félix Tobar (Philosophy, McGill) and Raimo Tuomela (Philosophy, University of Helsinki). I also appreciate the patience of Jan Hattink and Mrs N. Jones, both with the Reidel Publ. Co. I gratefully acknowledge a research grant from the Social Sciences and Humanities Research Council of Canada. Last, but not least, I thank my housekeeper Mrs Daniela Konieczny.

June 1983

SPECIAL SYMBOLS

$\neg p$	*not-p*
$p \mathbin{\&} q$	*p and q* (*conjunction*)
$p \vee q$	*p or q* (*disjunction*)
$p \Rightarrow q$	If p, then q (*implication*)
$p \Leftrightarrow q$	If p, then q, and conversely (*iff*)
$A \vdash B$	Premises A *entail* conclusions B
$=_{df}$	Identical by *definition*
$\{x \mid Fx\}$	The *set* of objects possessing property F
$\emptyset$	The *empty set*
$a \in A$	Individual *a belongs to* set A
$A \subseteq B$	Set A is *included* in set B
$A \cup B$	The set of objects in A *or* in B
$A \cap B$	The set of objects in A *and* in B
$A - B$	The set of objects in A but *not in* B
$A \Delta B$	The set of objects in A *or* in B but *not in both*
$\langle a, b \rangle$	The *ordered pair* of a and b
$A \times B$	The *cartesian product of* A and B, i.e. the set of ordered pairs $\langle a, b \rangle$, where a is in A and b in B
2^A	The *power set* (family of all subsets) of set A
$\lvert A \rvert$	The *cardinality* (numerosity) of set A
$\mathbb{N}$	The set of *natural numbers* (0, 1, 2,...)
$\mathbb{R}$	The *real line*
$\mathbb{R}^+$	The set of *non-negative real numbers*
$f: A \rightarrow B$	The *function* f maps set A into set B
$f(x)$	The *value* of function f at x
$F = \langle F_1, F_2, \ldots, F_n, \ldots \rangle$	A state function for some system
R & D	Research and development
S & T	Science and technology

INTRODUCTION

In this Introduction we shall state the business of both descriptive and normative epistemology, and shall locate them in the map of learning. This must be done because epistemology has been pronounced dead, and methodology nonexisting; and because, when acknowledged at all, they are often misplaced.

1. DESCRIPTIVE EPISTEMOLOGY

The following problems are typical of classical epistemology:

(i) What can we know?
(ii) How do we know?
(iii) What, if anything, does the subject contribute to his knowledge?
(iv) What is truth?
(v) How can we recognize truth?
(vi) What is probable knowledge as opposed to certain knowledge?
(vii) Is there a priori knowledge, and if so of what?
(viii) How are knowledge and action related?
(ix) How are knowledge and language related?
(x) What is the status of concepts and propositions?

In some guise or other all of these problems are still with us. To be sure, if construed as a demand for an inventory of knowledge the first problem is not a philosophical one any more than the question 'What is there?'. But it is a genuine philosophical problem if construed thus: 'What kinds of object are knowable—and which ones are not?' However, it is doubtful that philosophy can offer a correct answer to this problem without the help of science and technology. For example, only these disciplines can tell us whether man can know not only phenomena (appearances) but also noumena (things in themselves or self-existing objects).

Problem (ii) used to be called that of the sources of knowledge: do we know by revelation, intuition, sense experience, action, or reasoning? It may now be reformulated as the problem of cognitive mechanisms, and it is of interest to psychology, not only to philosophy.

Problem (iii)—about the possible contribution of the subject—used to trigger automatic responses, in particular 'Nothing' (empiricism) and 'Everything' (rationalism). It can now be investigated with the help of psychology.

Problem (iv) is ill-conceived, for it presupposes that there is a single kind of truth. Actually there are at least four kinds of truth (or four kinds of proposition to which a truth value can be assigned): logical, mathematical, factual, and philosophical. Logical and mathematical truth have become the property of logic and metamathematics. The problem of philosophical truth belongs to both descriptive and normative epistemology. And truth of fact, the concept occurring in all inquiries into matters of fact, is investigated by semantics—and perhaps can also be approached by psychobiology.

Problem (v) is that of truth tests and criteria, and is therefore best left to normative epistemology or methodology.

Problem (vi) is that of the fallibility of factual knowledge—or, to put it in positive terms, of the corrigibility of hypotheses and data. And it may or may not be linked to the probability calculus. (It is not so linked in the present work.)

Problem (vii) is that of the scope of pure reason, the nature of formal science, and the existence of (true) a priori statements of fact—hence it is actually a whole family of problems.

Problem (viii) is central to the philosophy of technology as well as to dialectical materialism and pragmatism. Any examination of it should include an analysis of the role of knowledge in the design and implementation of plans, as well as a discussion of the value of praxis in posing cognitive problems or even in evaluating truth claims.

Problem (ix) is at the very core of the philosophies of language and mind. However, it should be handled with an eye on developmental psychology, neurolinguistics, and psycholinguistics.

Finally problem (x) belongs also to semantics and ontology, as well as to the philosophy of logic and mathematics.

Note that all of the above problems continue to draw the attention of some people and may thus be said (metaphorically) to be alive. (A problem is "dead" if no living being deals with it.) And they are "alive" because they continue to be open, i.e. not fully solved. Note also that epistemology has ceased to hold a monopoly on those problems: it shares them with other disciplines, be they other branches of philosophy or special sciences. In other words epistemology is (if not *de facto* at least *de jure*) no longer an independent discipline. The moral is clear: Do not pretend that epistemological problems can be attacked without the help of allied disciplines, in particular (though not exclusively) semantics, psychology and social science.

Nor are the above the only epistemological problems left, not even the only classical ones. Here is a short and haphazard list of problems on which epistemologists and sociologists of knowledge are currently working:

(xi) What is the role of mathematics in the generation of factual knowledge?
(xii) What is rationality?
(xiii) Can belief and plausible reasoning be regimented or formalized?
(xiv) What are problems, methods, approaches, hypotheses, theories, and rules?
(xv) What are the peculiarities of tacit knowledge (*know how*) and of explicit knowledge (*know that*)?
(xvi) What are the commonalities and peculiarities of description, classification, explanation, and prediction?
(xvii) What are basic science, applied science, and technology?
(xviii) What, if any, is the role of morality in inquiry?
(xix) How does the social matrix influence the cognitive activities?
(xx) What are the characteristics of learning (or inquiring) communities?

Note that, whereas traditional epistemology focused on knowledge, modern epistemology is also interested in the applications of knowledge. Second, whereas classical epistemology was concerned solely with the knowing subject and his (never her) accomplishments, or both, modern epistemology is also interested in learning communities as well as in the social function of cognition and in the social constraints on it. Consequently some of its problems are shared by social science, in particular the sociology of knowledge and social psychology. Recalling our comments on some of the typical problems of traditional epistemology, we must conclude that epistemology is only one of the cognitive sciences and it has a considerable overlap with its sister disciplines, in particular psychology (cognitive, developmental and evolutionary) and sociology (in particular social psychology and the sociology of knowledge).

2. NORMATIVE EPISTEMOLOGY (METHODOLOGY)

Unlike descriptive epistemology its normative partner, methodology, has only weak roots in Antiquity and the Middle Ages. Leaving logic aside, they amount to a handful of rules, such as Plato's injunction to shun opinion (*doxa*) and seek only certain knowledge (*episteme*), Aristotle's practice of defining everything, Hippocrates' recommendation to abstain from supernaturalistic explanation, and Ptolemy's advice that astronomy be restricted to describing phenomena (appearances).

The idea of a universal method for acquiring knowledge did not appear until *ca.* 1600. Discoursing on method became then fashionable, even a craze. There was hardly a scholar who doubted that, if only the right method could be found, mankind would attain instant wisdom. Bacon swore by induction and Descartes by conceptual analysis and deduction from indubitable first principles. Leibniz dreamed not only of a logical algorithm (*characteristica universalis*) but also of an *ars inveniendi* leading securely to first principles. It was a time of mythodology and methodolatry rather than methodology. The illusion lasted nearly three centuries.

Methodology proper did not come until the first modern philosophers of science, in particular Whewell (1847). Although some investigators deny the existence of methodology, it is easy to find methodological problems, many of which have not yet been given satisfactory solutions, or at least generally accepted ones. Here is a sample of rather classical problems of this kind.

(i) Is there a single best way of advancing knowledge and, if so, which is it?
(ii) What is the scientific method?
(iii) What kinds of convention do we stipulate and which are their roles in inquiry?
(iv) What are the rules of correct definition? And are there creative definitions?
(v) What are the principles of correct classification?
(vi) What is the role of regulative (or heuristic) principles in inquiry?
(vii) What kinds of theory should we prefer: descriptive (phenomenological) or explanatory (mechanismic), deterministic or probabilistic, single-level or multilevel?
(viii) What is the point of axiomatics?
(ix) What is testability: confirmability, refutability, or either?

(x) If theories are tested as wholes, how can we spot their false components?

All of these problems are still topical and some of them are still open. Whereas some of them, in particular the first two, are discussed even in bull sessions, others are the subject of technical papers or books. But all of them are likely to be faced, sooner or later, by all investigators. For example (v), or Aristotle's problem, is very much alive among biologists, particularly in connection with numerical and evolutionary taxonomy. Problem (vi), Kant's, comes up in every discussion of correspondence principles. Problem (vii) is confronted by anyone who proposes to build a factual theory or model. Problem (viii), Hilbert's, is discussed by both friends and foes of axiomatics. Problem (ix) is the bone of contention between confirmationists and refutationists. And Duhem's problem (x) is faced by any investigator in the presence of some evidence against an otherwise well confirmed theory.

Here is a random sample of methodological problems that have come more recently to the fore:

(xi) Are properties dispensable? If not, how are they to be represented?
(xii) Can there be any techniques of theory construction?
(xiii) What are the advantages of the reduction (deduction) and of the merger (synthesis) of theories and entire disciplines?
(xiv) How should hypotheses and theories be evaluated? In particular, is empirical confirmation necessary and sufficient?
(xv) Do we have to test all the alternative hypotheses that might account for a given group of facts, or only those enjoying some empirical or theoretical support?
(xvi) How are revolutionary new ideas or procedures to be evaluated? Do they have to be compatible with some of our previous knowledge or can they be totally deviant?
(xvii) What would be the value of measurement and experiment if the experimenter had powers of psychokinesis and precognition?
(xviii) What can be the value of empirical tests if they are designed with the help of theories?
(xix) How should methods be tested?
(xx) How should the rules of statistical testing (e.g. for significance or for randomness) be tested?

Problem (xi), prompted by the nominalist mistrust of properties and their conceptualization (attributes), is both philosophically and technically interesting. Problem (xii) was initially raised by the believers in the possibility of fashioning recipes for inventing, and has recently been revived by some computer enthusiasts. (If empiricists are right in holding that theories are data packages or distillates, why not build or program an electronic theorist?) Problem (xiii) comprises the questions of reductionism and of the unity of science. Problem (xiv) questions the empiricist tenet that empirical confirmation is not only necessary but also sufficient to canonize hypotheses and theories. Problem (xv) questions the refutationist conviction that experimental scientists have all the time in the world to try and refute any hypotheses or theories that may occur to us. Problem (xvi) is that of weighing scientific revolutions and distinguishing them from crackpot proposals. Problem (xvii) suggests that experimental science presupposes the falsity of parapsychology—which in turn poses the problem of the empirical testability of belief in the paranormal. Problem (xviii) amounts to this: Are empirical procedures contaminated by theory to the point that they have no test power? And the last two problems pose the difficult question of evaluating the goodness of methods and rules.

Let the above sample suffice to show that methodology can be neglected only at the risk of making bad mistakes. And note the salient characteristic of methodological problems in contrast to problems in descriptive epistemology (Section 1). Whereas the latter are questions of fact—How do we know X?, What is cognitive item Y?, and the like—methodology handles typically value problems—What is X worth?, What is the correct way of doing Y?, and the like. Consequently, whereas an epistemological problem is answered by a description, a definition, or a theory, a methodological problem is answered, in the last analysis, by a value judgment or by a rule of procedure—either of which must in turn be justified in terms of theory, experiment, or praxis. In short, methodology, like logic and decision theory, is a normative discipline.

3. EPISTEMOLOGY AND BIOLOGY

All cognitive activities, from sniffing and exploring to theorizing and forecasting, are biological functions—as well as social ones in the case of social animals. They are all aspects of the adaptation of animals to their environment as well as of their activity in altering their environments to suit their needs. Hence biology is, or ought to be, interested in cognition, and all the cognitive sciences are, or ought to be, based on biology.

The view that cognition is a biological process emerged in the late 19th century, which saw the beginnings of experimental psychology as well as of comparative (or evolutionary) psychology, later to be supplemented by developmental (or genetic) psychology. Perception ceased to be a subject of philosophical speculation to become a problem for physiologists and experimental psychologists. Even problem solving and other higher mental functions became eventually the object of experimental investigation and, more timidly, mathematical modelling. Darwin, Helmholtz, Mach, Lloyd Morgan, Yerkes, Köhler, Piaget, Békesy and Hebb were among the pioneers of the biological approach to psychology and, in particular, the study of cognitive abilities. Today this study is pursued vigorously by physiological psychology (cf. Hebb, 1966; Milner, 1970; Bindra, 1976). This approach to cognition must not be confused with *cognitivism*, or the information processing view, just as the study of behavior must not be identified with behaviorism. Indeed the gist of cognitivism is that biology is irrelevant to the understanding of cognition, whereas computer science is essential to it (cf. Simon, 1979; Pylyshyn, 1980).

The *rapprochement* between psychology and epistemology, on the one hand, and biology on the other, was not limited to the scientific community but fascinated also some philosophers. Thus Nietzsche, the real founder of pragmatism, held that lies may be just as useful for life as truths, and claimed that the sole justification for research lies in its usefulness to preserve life. Likewise Spencer is the author of the famous dictum "Science is for life, not life for science". (Many contemporary statesmen and bureaucrats hold the same narrow-minded view of science without having read either Nietszche or Spencer: we keep reinventing falsity.) Spencer also wrote the celebrated sentence echoed in our days by Konrad Lorenz: "What is *a priori* for an individual is *a posteriori* for a species". (That is, the individual does not have to start from scratch, for it inherits a number of traits won in the course of evolution.) And Mach—noted for his important discovery that sensation is a function not only of stimulation but also of inhibition—wrote occasionally of the "transformations and adaptations" of thought. He also wrote about "the adaptation of thought to sensation" (which he regarded as the sole firm source of knowledge), as well as about the conflict between the two (for him the sole source of problems). But he did not spell out how cognitive behavior can be beneficial or harmful, let alone how selection could uproot incorrect cognitive habits.

Neither Nietzsche nor Spencer nor Mach may be said to have built a biological psychology, let alone an evolutionary one. (See Čapek (1968) for the opposite view.) The same holds for Peirce, another thinker influenced by Darwin's theory, and who stated that the truest beliefs are those that "live" longest—an idea refuted by the persistence of superstition. Nor is evolutionary epistemology related to Popper's analogy between natural selection and refutation, let alone to his speculations on disembodied "world 3" items (Popper, 1972). Indeed the theory of evolution applies only to concrete systems, namely biopopulations, not to disembodied objects such as ideas in themselves (Bunge, 1981a).

If epistemology is to become scientific it will have to learn not only from neurophysiology and physiological psychology but also from developmental (genetic) psychology and from whatever evolutionary biology has to say about cognition. That is, it will have to include evolutionary epistemology. So far this is little else than a thesis and a program. The thesis is this: "Our cognitive apparatus is a result of evolution. The subjective cognitive structures are adapted to the world because they have evolved, in the course of evolution, in adaptation to that world. And they match (partially) the real structures because only such matching has made such survival possible" (Vollmer, 1975, p. 102). This is a programmatic thesis: it orients a whole research project that has still to be implemented not only with more observations in comparative psychology and ethology but also with theoretical synthesis and speculation, as well as the conceptual clarification (of, e.g. the hazy notions of cognitive structure and real structure). However immature, the project of evolutionary epistemology is well grounded, not wild: it fits in with evolutionary biology.

4. EPISTEMOLOGY AND PSYCHOLOGY

Except for physiological psychologists and the rare zoologist, ethologist, or neuroscientist, cognition is usually regarded as a suprabiological phenomenon and studied separately from the nervous system. One main reason for this non-biological approach is the persistence of the ancient myth of the immaterial mind. This myth is not only a component of most religions and popular world views but also of most psychological doctrines (in particular psychoanalysis) and most philosophies of mind. (For a defense see Popper and Eccles (1977), and Eccles (1980); for criticisms see Bindra (1980), Bunge (1980a, 1981a), and Hebb (1980).)

The detachment of cognition from its organ, namely the nervous system, deprives psychology and epistemology of substance and depth: it is like discoursing about the weather as if it were something different from the state of the atmosphere. By the same token it prevents psychology and epistemology from benefiting from the findings of neuroscience and, in general, it isolates them from all the other cognitive fields. (Isolation is characteristic of protoscience and pseudoscience.)

If mind and matter are distinct substances, then it is hard to understand how the former can get to know the latter, except by adopting some form of idealism. In this case matter does not exist except as a figment of our own mind, and the acquiring of knowledge about anything is reduced to the mind knowing itself or other minds, whether individual or supraindividual. This may work for logic and mathematics but it fails to account for natural science and technology, as in these fields one must take the real world for granted if one wishes to learn something about it. In fact, there would be no point in exploring the world unless it were out there all by itself. In particular we would waste no time experimenting.

On the other hand materialism has no trouble understanding, at least in principle, how a material system (the brain) can get to know something about other material things or even about itself. Indeed, according to materialism (and physiological psychology) every cognitive process is a string of events in some central nervous system. So it may be imagined that it can match other material processes, much as an electrocardiograph transduces voltage variations into graphs, or a radio receiver transforms electromagnetic waves into sound waves. Moreover, materialism happens to be the ontology of modern science, which, far from countenancing disembodied or ghostly entities, assumes that all existents are lawfully changing concrete (or material) things, though not necessarily of the same kind. (See *Treatise*, Vols. 3 and 4.) For these reasons we choose materialism, and more particularly scientific materialism (Bunge, 1981a), as the general ontological view which our epistemology is to fit.

This approach to the study of cognition contrasts with both traditional mentalism and neomentalism, or the philosophy of mind adopted by most workers in the so-called *cognitive science*. This is the collective name of three disciplines concerned with cognition: cognitive psychology, linguistics, and artificial intelligence. Whatever the accomplishments of these fields, they share an important shortcoming, namely, that all three ignore the nervous system and are therefore isolated from neuroscience and psychobiology. Furthermore, cognitivism has produced no new theoretical models and it has ignored motivation and response production, so it cannot possibly offer a comprehensive framework for psychology (Bindra, 1982). In particular, talk about human information processing and computing is just a metaphor and, as such, no substitute for a theory. (Recall Hobbes' characterization of metaphor as *ignis fatuus.*)

Nor is our approach in sympathy with behavioristic psychology. The investigation of cognitive processes includes the observation and measurement of behavior but cannot be restricted to it because the motivations, intentions, cogitations, goals and plans of the inquiring subjects are not observable. Besides, what the inquirers do is totally unintelligible to an observer who does not have a similar background. For example, a chemist, a chemical engineer and an alchemist may wear white laboratory coats, handle roughly the same instruments and the same chemicals, and even go through similar motions, while doing entirely different things because they think differently and have different goals and methods. For this reason the fashionable anthropological and sociological studies of the scientific community (e.g. Latour and Woolgar, 1979), when limited to observing the behavior of scientists, are useless when not positively damaging to the science of science.

5. THE PLACE OF EPISTEMOLOGY

Many disciplines besides descriptive and normative epistemology study cognition and its outcome, i.e. knowledge. Zoology and ethology are interested in cognition; so are neuroscience and psychobiology (or biopsychology), as well as the non-biological approaches to cognition, in particular neomentalism, linguistics, and artificial intelligence. Nor are these the only members of the family that could bear the hybrid name *cognitology.* All of the social sciences are interested in cognition and knowledge: in the former because learning is largely a social process, in the latter because knowledge is a social force—or, rather, people who know something out of the ordinary can affect the behavior of others. In particular, anthropologists study the functions of the learning professionals, be they shamans or molecular biologists; archaeologists conjecture what ancient peoples must have known in order to manufacture the artifacts that are dug out; social psychologists investigate the social constraints on cognition as well as the effects of knowledge on social structure; and historians—particularly historians of science, technology, or the humanities—are interested in the traditions and revolutions in modes of inquiry and belief, as well as their relations with environmental, demographic, economic and political factors.

All the members of cognitology have a common referent, namely the inquiring system (individual or group). Therefore there is—inevitably and happily—some overlap between the various sciences of cognition and knowledge. However, a common reference does not ensure identity, for one and the same subject matter can be studied from different viewpoints—i.e. one can ask questions of different kinds about one and the same entity. This holds, in particular, for the scientific and the philosophical approaches to cognition and knowledge. For example, whereas the scientist may study perception and perceptual illusion as sources of knowledge and error respectively, the philosopher may also study the scope of perception, the nature of perceptual knowledge and its differences from conceptual knowledge, as well as the contrast between appearances (as presented in perception) and reality (as conjectured by theory). Whereas the scientist may be interested in the way children come to know about objective constancies (e.g. conservation laws), the philosopher may puzzle the nature of law statements, their relation to objective patterns, and the role of such statements in science and technology. And whereas the scientist may investigate the origin—psychological or historical—of theories, the philosopher may study the very nature and role of finished theories, as well as the conceptual (rather than psychological or cultural) differences between them.

Both approaches to cognition and knowledge, the scientific and the philosophical, are necessary. The scientist could not even start studying, say, the process of hypothesis formation (in some brain and under certain social circumstances) unless he had a reasonably precise and correct idea of what a hypothesis is—which idea it behoves philosophers to exactify. And the philosopher should be happy to learn that somebody studies the genesis, evolution, and demise of hypotheses, not only in highly educated human adults but also in children, primitive man, and even in some subhuman species.

Cognition and knowledge can then, nay must, be studied *both* scientifically and philosophically. The two approaches are needed because they are mutually complementary and they stimulate and control one another. (Only bad science is the enemy of good philosophy, and bad philosophy the rival of good science.) Moreover there is no clear demarcation between scientific and philosophical epistemology, and none should be invented.

(Likewise there is no borderline between science and ontology: see *Treatise*, Vol. 3, Introduction.) This way of conceiving of epistemology is likely to advance our knowledge of cognition and knowledge, for each partial view can be allowed to enrich and check the other.

An additional advantage of conceiving of philosophical epistemology as a member of the large family of cognitive sciences (or *cognitology*) is this. Ordinarily epistemology is regarded as being far removed from both ontology and ethics. In our perspective cognition is only a special kind of biological process, and therefore it is an object of study of the ontology of organisms; and organisms capable of sharing knowledge are members of some society or other, and therefore the object of study of the ontology of society. Thus any reasonably true generalizations about cognition may be placed in the intersection of the science and the philosophy of cognition.

Nor is epistemology alien to ethics or the study of morality. Indeed normative epistemology is about rules of correct (or successful) inquiry; and rules, unlike laws of nature, can be either obeyed or broken with honest or dishonest intentions. Besides, all knowledge is valuable in one way or other; and anything valuable can be well used or ill used, shared or stolen—as well as traded and faked. The pursuit of knowledge must then involve a moral code. In fact it does involve one: recall the commandments to prefer truth to error, to check conjectures, not to make up data, to seek criticism, to acknowledge truth in the rival and error in the friend, to share information, and so on. This code of inquiry intersects with methodology: every correct procedure of inquiry is intellectually honest even though it may be morally objectionable on other grounds.

What about logic and mathematics in their relation to epistemology? These two formal sciences provide the backbone of all the other sciences but they do not investigate cognition and they are not in a position to discriminate factual truth from factual error. In short, they are not members of cognitology. To be sure, logic used to be regarded as the *organon* of inquiry and thus as identical with methodology. But we have learned since the beginning of the modern period that logic may at most discover (logical) error: it is not a guide of inquiry but a constraint on it. We now tend to conceive of logic as the intersection of mathematics and philosophy, as well as a tool of conceptual analysis and criticism in all cognitive fields.

In conclusion, epistemology is not an independent discipline. It must make use of logic and can make use of mathematics, and it belongs to the family of cognitive sciences. Moreover it has considerable overlaps with all

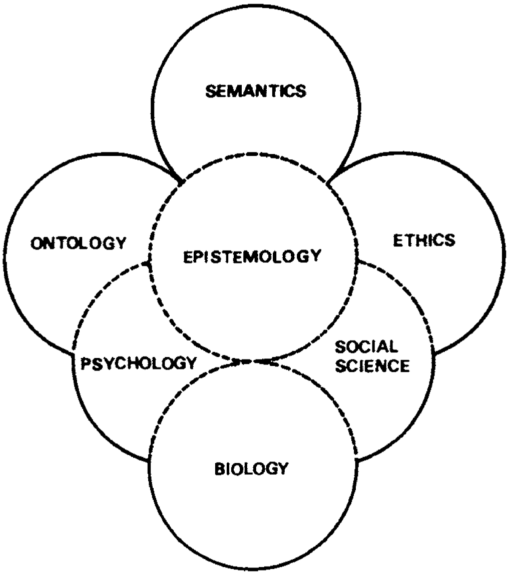

Fig. 0.1. The place of epistemology among the cognitive and philosophical sciences. Note the overlappings with neighbouring fields and the lack of clear cut boundaries between them.

of these disciplines as well as with ontology and ethics, not to mention semantics, from which it is often indistinguishable. See Figure 0.1.

6. USES OF EPISTEMOLOGY

There should be no need to justify research on cognition and knowledge: only barbarians or yahoos would question the worth of inquiring for the sake of knowing. But since scientists and philosophers are besieged by barbarians and yahoos, it won't hurt to argue for the practical uses of such studies.

To begin with, learning theory, though still in its infancy, has already had a profound impact on the theory and practice of teaching. (See Suppes (Ed.), 1978.) Secondly, behavior therapists are having some success in correcting bad habits, in particular bad cognitive habits, on the basis of the hypothesis that whatever has been learned can be unlearned. (See Bandura, 1974; Wolpe, 1976, 1978.) Thirdly, neurologists have started to cope with learning disabilities attributable to congenital neural defects or brain injuries. (See Hécaen and Albert, 1978; Pincus and Tucker, 1978.) In short the psychology of cognition, though still very young, has proved its practical usefulness. Much more can be expected from it if it sheds the myth of the immaterial mind as well as the superficiality and dogmatism of behaviorism.

The social studies of cognition and knowledge have made important inroads as well (cf. Merton, 1973). The most important of them has been showing (not just asserting) that social circumstances condition our mode of perceiving, thinking, and evaluating, so that cognition and knowledge cannot be adequately understood except in their social context. Moreover it has now become clear that, at least in man, knowledge and sociality are coextensive: neither exists without the other. This discovery has had a profound impact on the history of science and technology, which until relatively recently followed the pattern of the history of ideas, investigating ideas in a social vacuum. (Inevitably, the discovery of the social dimension of cognition has led to sociologism, or the neglect of the brain as well as individual circumstances.)

Philosophical epistemology is a little harder to defend nowadays. However, if we care for science, technology, and the humanities, we should also care for their epistemological presuppositions—such as that there is an independent reality and that it can be known if only in part. We should dig up, cleanse, analyze, and systematize such principles. (For a short list see Ch. 15, Section 3.1.) It would seem obvious that, the better we know how we can get to know, the better we can improve (or block) the learning process, particularly in science, technology, and the humanities. So, a study of the epistemological presuppositions of research, as well as of any other tacit assumptions of scientific and technological research, should pay off in practical results.

As for normative epistemology, it is often claimed that it is no more needed for doing science or technology than a knowledge of grammar is needed for writing well or of logic for thinking correctly. True, some people untutored in logic and grammar think and write well, and most successful scientists and technologists have not been exposed to methodology. However, it is also true that the study of grammar improves good writing, that of logic good thinking, and that of methodology good research. Most people untutored in logic and methodology are prone to incur fallacies and find it difficult to design research strategies even for solving simple problems. In his classic *Thinking* (1958) Bartlett concluded that "especially with naive, although intelligent searchers, it is most likely that the method of search adopted will be an uneconomical one".

However, most scientists and technologists are indifferent to, when not contemptuous of, methodology. Philosophers tend to impute this attitude to excessive specialization, lack of philosophical curiosity, or even illiteracy. Scientists and technologists feel on the other hand that methodologists misrepresent what scientists and technologists do or ought to do (e.g. Medawar, 1969). Actually the situation is much worse than either party thinks, for *both* are right. Indeed there seem to be few if any persons capable of giving a truthful and balanced account of the actual conduct of inquiry—even of their own. Author *A* believes only in logic, *B* only in intuition; *C* swears by induction and *D* by deduction; *E* by experiment and *F* by theory; author *G* is a gradualist and *H* a catastrophist with regard to the evolution of knowledge; thinker *J* ignores society altogether and *K* places knowledge in society—and so on and so forth. Every one of them can cite examples in his favor, so neither of them is totally wrong. But none of them has built a system accommodating the many and apparently conflicting features of inquiry: each of them offers a one-sided view, and each is anxious to have it accepted as his own original *ism*.

We must try and strike a golden mean between *methodolatry* and *methodoclasm*. The former is the view that method is more important than product. (Paradigm: the Chinese dictum "Do not give me a fish: instead, teach me how to fish.") Extreme methodolatry will promote the teaching of methods separate from subject matter, and so the student will learn neither. On the other hand methodoclasm holds that only knowledge is important, not how we come to know. (Paradigm: "What matters with a piece of news is whether it is true or false, not the means—hearsay, reading, intuition, etc.—we come by it.") Extreme methodoclasm will promote teaching the results of research with neglect of the way research was initiated, planned, conducted, and evaluated.

A balanced view will hold that both the process of inquiry and its product are worthy of study. This view has two advantages. One is that it allows one to examine and evaluate methods in the light of results and conversely—the virtuous circle principle. (See Bunge, 1962; Rescher, 1977.) Another advantage is that a study of methodology serves to rectify a number of misconceptions about inquiry. Some scientists have been known to be busy on problems other than those they believed they were investigating; at a loss to formulate the most obvious hypotheses or even reluctant to make any conjectures; incapable of clarifying key notions they used daily; totally uninterested in neighboring fields; ignorant of the ultimate goals of scientific research; contemptuous of theory or, more rarely, of empirical test; believing that all the mathematics they need is a handful of statistical recipes—or, on the contrary, that mathematics suffices for science. Any such scientist would profit by some methodology. And even the most experienced and successful researchers can benefit from pondering, once in a while, over such rules as: "Place your problem in a wider context", "Look for deeper (non-apparent) variables", and "Do not underrate chance". (See Ch. 15, Section 3.2, for a short list of regulative principles of research.)

7. CONCLUDING REMARKS

Epistemology teems with open problems: a sign that it has a right to life. But epistemology is still immature: a sign that it has a long way to go. It cannot go it alone and in fact it has interacted vigorously with natural science, in particular physics, since the 17th century. But until recently epistemology has had only very weak ties with evolutionary biology, neuropsychology, and social science—not surprisingly, for these came long after epistemology was born.

Epistemology must mesh in with biology, psychology, and social science, because the learning process happens to occur in and among animals. The immaterial and isolated (and male and adult) knowing subject of traditional epistemology must be replaced with the inquiring brain, or team of brains, embedded in society. The unchanging mature mind must be replaced with developing and evolving animals exploring their environment as well as themselves, and changing both with the help of the knowledge gained in such inquiries. Epistemology, in sum, must be biologized and sociologized.

However, this proposed reconstruction of epistemology with the help of biology, psychology, and social science, should not be taken as a pretext for neglecting the epistemological problems that can be handled independently. Thus regardless of whether or not conjecturing and jumping to conclusions are inborn human dispositions; regardless of the particular neural systems that do the conjecturing and the jumping to conclusions; and regardless of the way social circumstances stimulate or inhibit such brain processes, hypotheses and inferences have certain logical, semantical, and methodological properties (e.g. generality, factual reference, and testability) that can and must be studied separately from the corresponding concrete biological and social processes. Likewise we do not need biology, psychology or social science to check whether a computation is correct or whether the components of an electric circuit have been assembled correctly.

In short, up to a certain point methodological inquiry can be pursued independently of descriptive epistemology. This relative independence explains why we have been able to learn (and stipulate) something about the *correct* way of going about forming and combining concepts and propositions, classing, comparing, analyzing, etc. without really knowing much about the neurophysiology (or even the global psychology) of such operations. Nevertheless this situation is anomalous and reminds one of the engineering feats of the ancients, which had no scientific basis, rather than of modern technology, which is science-based. We may conjecture that a more intense and deeper scientific investigation of cognition, and in particular of the neurophysiology of thinking, may bring about a revolution in methodology or at least a more intimate understanding of the relation between the *is* and the *ought* of knowledge. But for the time being we are faced with the relative independence and more advanced state of development of normative epistemology. This explains why it gets the lion's share in this book.

PART I

COGNITION AND COMMUNICATION

CHAPTER 1

COGNITION

This book is about knowing and knowledge, error and ignorance: about the cognitive process, its pitfalls, and its outcome. When one perceives or conceives an object, investigates it, manipulates it or evaluates it, one engages in a cognitive process. With some ability and luck—i.e. under suitable circumstances—one will learn something about the object of inquiry. Whatever one has learned in this process, added to what he may have known beforehand, is one's *knowledge* of the object.

The distinction between a cognitive process—in particular an inquiry—and its result at a given moment is an instance of the process-state distinction. (A process may be construed as a sequence of states: Vol. 3, Ch. 5, Section 2.3.1.) It is a useful distinction because, for certain purposes, the end result is of little interest, whereas for others it is all that matters. Thus the neuroscientist and the psychologist are usually more interested in the learning process—and its disruptions—than in its accomplishments, whereas the latter attract most of the attention of traditional philosophers as well as of historians. Here we shall be concerned with both.

We ask indeed *Who* (or *what*) *can know what, and how*? This complex question summarizes the problematics of all the disciplines—philosophical, scientific and technological—concerned with cognition or with knowledge. The first part of the question, namely *who* (or *what*) knows, is handled by psychology (both animal and human) as well as by the sociology and history of knowledge. The second part, i.e. *what* can get known, interests epistemology and the history of science, technology, and the humanities. And the third part, namely *how* (by what means, mechanisms, or methods) we may get to know, is addressed by all the cognitive sciences, particularly methodology.

There are three fruitful approaches to the study of cognition: the neurobiological, the psychological, and the philosophical ones. All three are concerned, each in its own way, with the same problematics: internal representation, imagery, conception, conjecturing, systematization, inference, problem solving, criticism, and their kin. The neurobiological study of cognition attempts to lay bare the neural mechanisms of cognitive processes. The psychological study tries to describe them at the molar or phenomenological level, i.e. without inquiring into their neurophysiology. And the philosophical (epistemological) study endeavors to elucidate those concepts, as well as to discover the contribution of the various modes of knowing to the common enterprise, which is the perfectible knowledge of the world, including ourselves and our cognitive abilities.

Of these three approaches the oldest is the philosophical one, and it is fair to say that philosophers have so far contributed no less to the science of cognition than either psychologists or neuroscientists. But it is also fair to say that the philosophy of cognition is now at the end of its tether: one can only grasp so much of reality without the help of experiment and modeling. Psychology took up the problem of cognition ever since it became an independent science. True, neither behaviorists nor psychoanalysts placed much value on investigating cognition, and both schools ignored that which does the knowing, namely the central nervous system. But other schools and fields, in particular primatology, comparative psychology, developmental psychology, and the Gestalt group, continued to work on cognition.

Interest in cognition has been stronger than ever since about 1960, both among psychologists and neuroscientists. However, many of the former have adopted a new form of mentalism, where analogies with artificial information processors are central whereas the nervous system is all but ignored. They hold cognition to be a matter of software (mind) not hardware (brain). We shall ignore this new version of the old doctrine of the soul and shall adopt instead the psychobiological approach sketched in Vol. 4, Ch. 4. (See also Bindra, 1976; Bunge, 1980a; Hebb, 1980.)

According to psychobiology (or neuropsychology) every mental function is a brain function, but the converse is false. (There are "household" functions, such as metabolism and the synthesis of proteins and hormones, which are nonmental.) This view unites psychology with biology and suggests a vast research project, both experimental and theoretical, that is only beginning to explain the mind and, in particular, cognition. (The project is not new, for it is found already in Henry Maudsley's *The Physiology of Mind* (1876), which gained a considerable readership but few followers.) Because this project is only in its initial stage, many of its hypotheses and theories are speculative, and it offers many more problems than solutions—a sure sign of youth in science. So, it should be judged not so much for its accomplishments as by its promise and philosophical soundness, as well as by the failure of its alternatives, namely mentalism and behaviorism.

1. The knowing subject

1.1 *The Cognitive Organ*

Looking for external objects and perceiving some of them (or forming the idea that we have failed to do so); watching for internal bodily signs and feeling them (or realizing that we failed to perceive them); learning motor skills and intellectual ones; forming concepts or propositions, questions or commands; identifying and classing, inferring and computing, criticizing and theorizing; puzzling and pondering, expecting and planning; speaking and listening to talk—all these and many more are *cognitive* acts or processes. They all generate, transform or utilize bits of knowledge.

Our initial assumption is that *every cognitive act is a process in some nervous system*, whether human or not. To put it negatively: *There is no knowledge in itself*, i.e. separate from the cognitive processes occurring in some nervous system or other. In particular there are no ideas except in brains of certain kinds—presumably those of mammals and birds. No autonomous ideas, i.e. ideas detached from brains, have ever been found and, if psychobiology is right, there can be none.

Our initial assumption is of course at odds with the idealistic tradition. We adopt the naturalistic (materialist) view that Platonic ideas, ideas in themselves (Bolzano, 1837), objective knowledge without a knowing subject (Popper, 1972), and objective mathematical reality (Putnam, 1975) are so many figments of the metaphysician's brain (Bunge, 1981a). Just as there is no motion apart from moving things, so there are no ideas in themselves but, instead, ideating brains. To be sure we may *feign* that there are ideas in themselves and in fact we must often make such pretense. We do so whenever we abstract from the real people who think up such ideas as well as from the personal and social circumstances under which they ideate. We may do so as long as we do not forget that we indulge in fiction, whether useful or idle. If in doubt that this is indeed a fiction, imagine the fate of human ideas upon a total nuclear holocaust.

All mental processes are cognitive operations but the converse is false. Thus reading and writing, drawing and often also calculating, involve sensory-motor activities as well as the manipulation of artifacts, in particular learning tools. Over the past four hundred years man has invented and manufactured thousands of learning tools, from microscopes to thermometers, from particle accelerators to high speed computers. All these artifacts are used as adjuncts to the nervous system of somebody, expert or lay: they enjoy no autonomy. Even an automated measuring device presupposes a design involving hypothesizing, and its supplies food for further thought; and even the most automatic of computations is but a link in a cognitive process occurring in some brain. Just as there is no robot work but only robot-aided work, so there is no automatic cognition but only computer-aided cognition.

Since cognition is a function of the nervous system, we must turn to neuroscience and psychobiology (physiological, developmental and evolutionary psychology) for its explanation. (Pure psychology, traditional or modern, can only supply some data and pose some problems about cognition. Genuine scientific explanation, unlike mere description and prediction, involves some mechanism or other—in this case some neural mechanism.) Now, the psychobiological study of learning suggests that learning consists in a change in the connectivity of some neuronal system or other. To put it negatively: If a behavior is unchanging (stereotyped, genetically programmed), then it is controlled by some system composed of neurons the interconnections of which do not change quickly over time. (To be sure these rigid systems are not unchangeable: they develop from birth on and deteriorate with old age. Moreover, if injured or even destroyed they can often reassemble somewhere else. But the point is that these changes are slow compared to the extremely fast changes in neuronal connectivity that we identify with mental processes.) In short, only *plastic* (or modifiable, or self-organizable, or uncommitted) neuronal systems are capable of learning anything. We call any such system a *psychon* (Vol. 4, Ch. 4).

Our first postulate, then, is that learning is an activity of plastic neuronal systems, or psychons. Our second assumption is that some animals do have psychons. (Exactly which species have them is for comparative psychobiology, or evolutionary psychology, to find out.) Our third, that all the psychons of an animal are coupled to one another forming a supersystem. Our fourth, that every animal endowed with psychons is capable of acquiring new biofunctions in the course of its life. (Apparently in man the processes of dendritic sprouting and formation of new synaptic connections stop only at the onset of senility. So, barring senility—which only about one out of five of us experiences—we can continue to learn new items throughout life.) Finally we decide to call *learned* any neural function involving a psychon that has acquired a regular connectivity, i.e. one that is constant or varies regularly rather than at random. A new connectivity may be formed by chance for the first time. If it consolidates, i.e. if there is recurrence or recall, we regard it as established or learned.

Imagine a group of neurons in a young child's cortex. There are three possibilities: (*a*) the neurons are committed, i.e. they form a (rigid) system or part of one, that is genetically programmed; (*b*) the neurons are available: they can associate in one or more ways, ephemerally or permanently, either in a constant manner or in a regularly varying one; (*c*) such association has already occurred. In the first case we say that the group of neurons in question has a rigid connectivity and therefore *cannot learn* anything; in the second, that it has a potential plastic connectivity and therefore *can learn* something; in the third, that it has already *learned* something, though it can presumably learn further items or unlearn some or all of them.

New neuronal systems can be formed during the lifetime of any animal endowed with plastic neurons; and some such systems may be consolidated by use whereas others can be weakened by disuse: see Figure 1.1. This is the *use–disuse* hypothesis, proposed by Tanzi, adopted by Ramón y Cajal, and refined and exploited by Hebb in his classical work *The Organization of Behavior* (1949). In another seminal work, *A Theory of Intelligent Behavior* (1976), Bindra proposed and applied a substantial modification of Hebb's idea of a neuron assembly: the psychons (which he called *pexgos*) need not have a fixed spatial location but may be itinerant, so that every mental act, even a repetitive one, may consist in the formation of a fresh psychon.

There is considerable empirical evidence for the hypothesis that neurons assemble into multineuronal systems, which in turn are organized into supersystems (Mountcastle, 1978; Szentágothai, 1978). There is also a fair amount of evidence for the hypothesis of plasticity (cf. Flohr and Precht (Eds.), 1981) and, in particular, for the hypothesis that "use" strengthens synaptic transmission. (See, e.g. Bliss (1979) and Goddard (1980) for both short term and long term changes in connectivity.) Finally, there is mounting evidence for the hypothesis that mental processes are processes in plastic neural systems (e.g. Baranyi and Fehér, 1981). All such

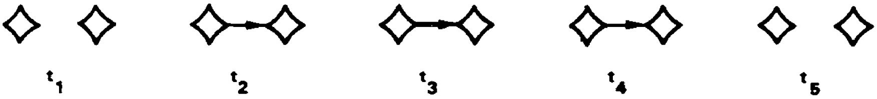

Fig. 1.1. Use–disuse. At time t_1 the two neurons are disconnected from one another. At t_2 one of them synapses onto the other: a system has been formed that may do things neither of the isolated neurons can. By t_3 the connection has been strengthened by use. At t_4 the coupling has weakened through disuse. At t_5 the connection has ceased through prolonged disuse or degeneration (e.g. pruning of dendrites).

hypotheses and data suggest a theoretical framework possessing considerable explanatory and heuristic power (Bunge, 1980a). However, this is just a beginning: we need plenty more detailed neural models, at least one for every cognitive function, and precise tests must be devised and conducted to check them. In any event, if we wish to understand the mind, and in particular cognition, we must give up the traditional arrogant armchair attitude and study the body, for minding is a brain process.

(Several mathematical models of learning psychons incorporate Hebb's use and disuse hypothesis. For example, Amari and Takeuchi (1978) postulate that the learning or self-organizing process consists in a change of the synaptic weights w_i associated to the input signals x_i according to the rate law

$$\tau \dot{w}_i = -w_i + cx_i H(w \cdot x - h),$$

where τ is a time constant, c a positive number measuring the learning efficiency, H the unit step function, h the threshold value, and $w \cdot x$ the scalar product of the synaptic weight vector w by the input vector x. If any of the stimuli are inhibitory, the corresponding synaptic weights are negative. By solving the above system of equations one finds that $w(t)$ is the weighted time average of $H(u)x(u)$ from $u = -\infty$ to $u = t$ with the weighting factor $(1/\tau)\exp[-(t-u)/\tau]$. By assuming that x is a random sequence of a certain type, a number of interesting consequences follow. But, because the neurons in this model are not supposed to fire unless they are excited externally, they are capable of learning only what they are taught. Plasticity, then, is not enough to account for spontaneous learning: if we wish to represent the creativity characteristic of conceptual learning we must include spontaneous neural activity. One way of doing so is to replace the above first order differential equation with a 2nd order one.)

In sum, we assume that the nervous systems of animals of certain species have plastic subsystems, i.e. neural systems with modifiable connectivity, as well as rigid neural systems. We also assume that every mental function is a process in some plastic neural system. For example the formation of a polysyllabic word, or of a sentence, of the form *abc*, probably consists in the sequential activation of neural units A, B, C, in the same order. This speculative hypothesis explains also thought and speech anomalies such as spoonerisms. Thus saying 'pointcounter' when intending to say 'counterpoint' might be due to the wrong timing of the psychons engaged in the production of 'counter' and 'point'. And in turn this time reversal might be caused by the temporary inhibition, or else the delay, of the first psychon, which inhibition (or delay) could be due to a number of factors, such as a strong coupling between the delayed psychon and a third psychon, or to external interference.

Our hypothesis that the nervous system is the organ of cognition is of course the very first postulate of any biologically oriented psychology and epistemology. This view is at variance with the fashionable cognitivist school and its computational or "functionalist" philosophy of mind (Putnam, 1960; Fodor, 1975, 1981; Pylyshyn, 1980). These are the basic tenets of cognitivism:

(i) Cognition is computation, and as such it is not a prerogative of brains: it can also be performed by computers. (Yet many cognitive processes, in particular perception and imagination, are not "intentional rule-governed phenomena" but occur spontaneously and unconsciously.)

(ii) Computation takes place in the mind, which is a kind of computer. (By pushing computation into an immaterial mind, the study of it does not fall under the jurisdiction of natural science. The fact that some computations can be simulated on computers does not prove that computation *in vivo* is essentially the same as its artificial mimicry.)

(iii) Any suitable theory of cognition is basically a theory of Turing machines. (This theory is so extremely simple that it cannot account for the humblest thing in the universe, such as an electron or a photon—let alone for a brain with its myriads of neurons and their plastic connections.)

(iv) Knowledge of the brain is irrelevant to understanding cognition and, in general, matter does not matter to mind. (Since cognitive processes are brain processes, neuroscience is essential to the advancement of cognitive psychology.)

(v) Artificial intelligence is the proper foundation for cognitive psychology, not the other way round. (So far this approach has produced only analogies. It is to be expected that, as neuropsychology advances, it will be able to guide work in artificial intelligence for, after all, imitation presupposes knowledge of the real thing.)

For the reasons advanced in parentheses, we regard cognitivist psychology not only as mistaken but as wrong-headed and paralyzing: as a collection of simplistic and superficial metaphors, a modern version of psychoneural dualism resulting in a further estrangement of psychology and epistemology from science, in particular biology. (For further criticisms see Bunge (1980a) and Vol. 6.)

1.2. *Brain States and Processes*

We have assumed that *every cognitive process is a process in some plastic subsystem of the nervous system of an animal.* Consequently an animal lacking a nervous system—be it small like an amoeba or large like a sponge—cannot know anything. It can of course react to stimuli of certain kinds and even act spontaneously—but so can any lump of matter.

We also assume that the nervous system, far from being a mushy thing, is a highly organized biosystem composed of subsystems each of which discharges certain peculiar functions in addition to the functions common to all living systems (such as metabolism and protein synthesis). Sometimes the specialization goes down to the individual neuron level. Thus the neurons in the mammalian visual cortex are so specialized that, whereas some of them detect only vertical lines, others react only to lines tilted at a 20° angle, and so on; still others detect short lines, wide lines, or what have you. (See Hubel and Wiesel, 1977; Gilbert and Wiesel, 1979.) In short the individual neurons of that kind analyze the incoming sensory inputs simply by selectively detecting some of their features. The integration or synthesis of these specialized activities is done by multineuronal systems. Traditional neuropsychology held that the brain is a sensory analyzer: we know now that it performs both the analysis and the synthesis of incoming stimuli, and also that it acts as a shock absorber for most of them, particularly the repetitive signals.

Whereas some cognitive processes occur in rigid (committed, wired-in, programmed) neural systems, others engage plastic neural systems as well, or perhaps exclusively. Thus the mere detection of ordinary stimuli requires only rigid neural systems, and so does the classing of stimuli into harmful, harmless, and beneficial. On the other hand locations or times, faces or letters, tricks or skills of any kind, presumably take plastic neural systems or psychons. The latter have been experimentally identified in a few cases. Thus Lindauer (1971) trained bees to forage at certain places, and then transplanted their tiny mushroom bodies into the brains of untrained bees. After recovery the latter made a bee line for the feeders. Knowledge can then be surgically removed and transplanted into a different animal—much to the chagrin of the mentalist.

The hypothesis that every cognitive activity is a process in a specialized neural system (i.e. the specific activity of it) can be elucidated as follows. To say that thing x is *active* at time t is the same as saying that at least one property of x is changing at t. Now, every property is lawfully related to at least one other property of the same thing: i.e. there are no stray properties. (For this ontological principle see Vol. 3, Ch. 2, Section 3.3.) So, if one property of a thing changes, other properties of the same thing will change as well: i.e. every change is multidimensional. For this reason we should always consider clusters of properties and, in principle, all the properties of a thing. If we do so we can speak of the states and the changes of state of the thing of interest. Every *state* is a list of properties, and every change of state of a thing is called an *event* occurring in the thing. The sequence or list of all the changes undergone by the thing during a time interval is called the *process* occurring in the thing over that interval. (There are no events or processes in themselves: every change is a change in some thing. Nonthings, such as immaterial souls and disembodied ideas, are in no state and *a fortiori* cannot change state.)

(A general and useful way of exactifying these ideas is as follows. First, represent each property of a thing of kind K as a mathematical function, in principle a time dependent one. (Never mind the other dependent variables for the moment.) Call F_K^i the function representing the ith property of thing of kind K. Next, collect all these functions into a list or n-tuple $F_K = \langle F_K^1, F_K^2, \ldots, F_K^n \rangle$, called the *state function* of an arbitrary member of K. The value $F_K(t)$ of the state function at time t may be pictured as an arrow representing the *state* of the thing at time t. As time goes by the tip of the

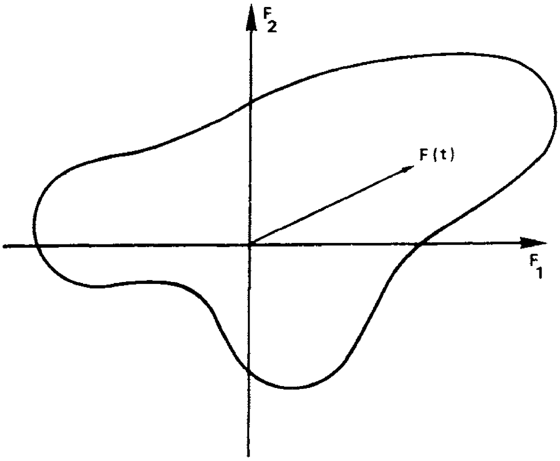

Fig. 1.2. State space for an (imaginary) thing characterized by two properties, represented by functions F_1 and F_2, combining into the state function $F = \langle F_1, F_2 \rangle$. The tip $F(t)$ of the "vector" F at time t represents the state of a thing of the given kind at t.

"vector" $F_K(t)$ spans a region of an n-dimensional space called the *state space* for things of kind K. (See Figure 1.2 and, for details, Bunge (1977a) or Bunge (1979a).) In other words, the "life history" of a thing of kind K is representable as a trajectory (or a bundle of trajectories) in the state space $S_K = \{F_K(t) | t \in T\}$, where T, a subset of the real line, is the set of all instants. The laws of things of kind K restrict the possible values of the state function, and therefore limit the state space for K's to a subset of the set of all logically possible states.)

(A state space for a species K represents all the lawful states of unspecified members of K. To individualize any state of a particular member of K we must specify its particular constraints and circumstances. Call F_K^a the state function representing an individual a of kind K. Knowing all the values of a particular F_K^a over a certain time interval amounts to knowing the history of the individual concerned during that interval. More precisely, we may say that the *history* of an individual of kind K over the time interval τ is representable as the graph of its F_K^a during τ. See Figure 1.3.)

(Now, the history of a thing may be eventful or nearly uneventful during a given interval. I.e., the state function F_K^a for a given individual a of kind K may change considerably or only negligibly over a given period. If the history is eventful we call it the *activity* (or process) of the thing concerned. Speaking formally, the activity of, or process in thing a during period τ, is

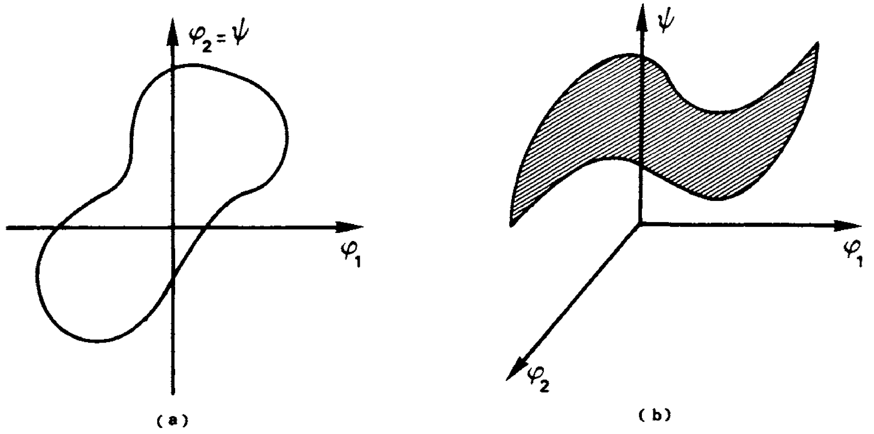

Fig. 1.3. Projection of state space of a plastic neural system. In (*a*) one of the biological properties (axes) is identical with a psychological one. In (*b*) the psychological property is some function of two biological properties—but is itself a biological property.

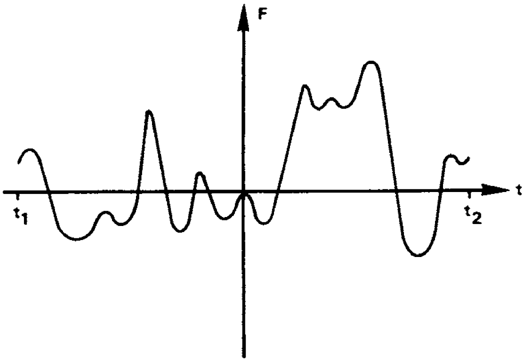

Fig. 1.4. History of a thing during the time interval $[t_1, t_2]$.

representable by the set of ordered pairs $\langle t, F^a_K(t)\rangle$ for t in τ, such that the rate of change $\dot{F}^a_K$ differs from zero:

$$\pi(a,\tau) = \{\langle t, F^a_K(t)\rangle \mid t \in \tau \ \ \& \ \ \dot{F}^a_K(t) \neq 0\}.$$

This graph represents the *total* activity of a over τ. See Figure 1.4.)

(In order to represent only the peculiar or specific activity of a thing we must subtract whatever other things do over the same period. Since we are interested in the specific activities of certain subsystems of an entire animal, we shall take "the other things" to be the parts of the animal other than the system of interest. To indicate that x is a *part* of b we write '$x \sqsubset b$' (Vol. 3, Ch. 1, Section 1). Thus the *specific* or *peculiar* process (or *activity* or *history*) going on in subsystem a of animal b during τ is representable by

$$\pi_s(a,\tau) = \pi(a,\tau) - \bigcup_{x \sqsubset b} \pi(x,\tau), \quad \text{with} \quad x \neq a,$$

where, for any sets A and B, $A - B = A \cap B$, '$\cap$' stands for intersection and '$\bar{B}$' for the complement of B. In other words, the specific function (or process) of system (e.g. organ) a in animal b equals its total function minus the total functions of all the remaining parts of the same animal. Thus imagine a system with only two components, and call them a and b. Suppose that their respective activities or processes during a given time interval are $\pi(a) = \pi \cup \pi_1$ and $\pi(b) = \pi \cup \pi_2$. Obviously their specific activities are $\pi_s(a) = \pi(a) - \pi(b) = \pi_1$, and $\pi_s(b) = \pi(b) - \pi(a) = \pi_2$.)

For example, seeing is the specific activity of the visual system, which in the higher vertebrates includes the visual cortex and is coupled to the motor system. (Every sensory system is a subsystem of its corresponding sensory-motor system. Thus looking is accompanied by saccadic movements, sniffing by puckering the nose, tasting by moving the tongue, listening by turning the head, and touching by moving a limb. After all, the sensory stripe is right next to the motor stripe in the cerebral cortex. In short, there is no perceptual learning without motor activity. In other words perceptual learning is not just a matter of receiving passively sensory inputs, but of combining a selection of such inputs with motor outputs: see Held and Hein (1963).) Likewise making a computation is presumably the specific activity of some psychon(s) in the association cortex; becoming conscious of one's own thoughts or feelings is presumably the specific activity of a neural system monitoring other neural components of the same brain, and so on.

Neuroscientists and psychobiologists are working on the problem of mapping the brain, in particular the cerebral cortex—i.e. of finding out what (neural system) does what (function or activity). This task was started by Penfield (1950) who, by stimulating electrically certain points of the cerebral cortex of waking patients, evoked in them various perceptions, images, memories, and thoughts. A suitable map of the brain would equate every cognitive function with a particular activity of some neural system or other (cf. Olds, 1975). Note that we have written *equate* not just *correlate* each cognitive function with a neural activity. Whereas the former expression suggests the identity of cognitive function and specific brain function, the latter expression suggests only a vague association between cognition and brain functioning in the style of psychophysical parallelism or interactionism. The dualist, to whom the mind is not a collection of brain functions but a separate substance, has no real use for brain mapping.

This mapping is such a formidable enterprise that it may be doubted whether it will ever be completed (Hebb, 1980). Consider: the plastic part of an individual human brain is composed of at least 1,000 million neurons. If each psychon has between 100 and 10,000 neurons, the total number of psychons is at least one million—and many times this figure if psychons are itinerant rather than fixed. Moreover it is well known that there are considerable differences among individual brains, so that the precise location of a particular cognitive function in one person is at most a very rough indication for its location in the next person. Nevertheless there has been considerable progress in this area over the past few years, as new techniques of imaging brain processes have been developed. These techniques have laid to rest the holistic hypothesis that the brain functions either as a totality or not at all.

TABLE 1.1
Cognitive deficits or disorders and their plausible neurophysiological explanation

Name or description	*Plausible explanation*
Blindness	Visual system damage or malfunction
Impaired vision	Multiple sclerosis, brain tumor, or dioptric defect
Visual agnosia	Lesion in occipital or posterior temporal regions or left hemisphere
Visual illusions and hallucinations	Lesions at any level in the visual system from eye to cortex
Deafness	Auditory system damage or malfunction
Unawareness of left half of body	Right parietal lobe damage or malfunction
Loss of attention	Reticular activation system or thalamus damage or malfunction
Amnesia	Bilateral hippocampal or diencephalic damage or other lesions or diseases
Loss of short term memory	Hippocampus damage or malfunction
Loss of curiosity	Frontal lobe damage
Loss of consciousness	Reticular activating system damage or malfunction
Aphasia	Wernicke or Broca area damage or malfunction
Dyslexia	Gyrus lesion
Agraphia	Temporal–parietal occipital lobe damage, retrorolandic lesion
Acalculia	Temporal or parietal lobe damage

Table 1.1 lists some of the cognitive deficits or disorders most frequently "seen" by clinical psychologists, psychiatrists, neurologists, and neurosurgeons. (See Pincus and Tucker, 1978; Hécaen and Albert, 1978.) We seem to know more about brain abnormality than about normality for two reasons: (*a*) the study of malfunction is one of the main ways of finding out what the normal function of a component is: we notice the light bulb in the dark staircase when it has burned out; (*b*) there are more researchers and means engaged in medical research than in neurobiological research—because of a science policy inspired in a pragmatist philosophy of science and technology.

Many workers speak of *information processing* where we speak of *brain processes*. That mode of speech is justified insofar as the nervous system does possess components capable of detecting, absorbing, transducing, or propagating signals throughout the system. However, it does not follow that the statistical theory of information is actually used to advantage to describe or explain such processes, and so no specific neural models need be constructed and tested. In fact information theory (Shannon and Weaver, 1949) applies only to messages transmitted through noisy channels and having definite probabilities of being received and decoded, whereas neuroscience and psychology are interested in *specific* biophysical, biochemical and biological processes occurring in the nervous system. When neuroscientists say that '*A* sends information to *B*', or that 'There is a flow of information from *A* to *B*', they ought to say simply that *A acts on B through C*. And when they write '*B* processes information coming from *A*' they ought to say simply: *A acts upon B*, triggering in *B* a process peculiar to *B* and different from any processes in *A*. After all they are dealing with systems of a very special kind, namely nervous systems, not—like the information theorist—with all kinds of information processors.

Besides, the brain is not just a processor of incoming stimuli: it also generates signals. True, S-R (or behaviorist) psychology, as well as "ecological" psychology (Gibson, 1979), hold that the brain does not create anything but picks up information from its environment. But of course any neuroscientist knows that the brain of the higher vertebrate has a constant autonomous activity. And any psychologist might argue that the view that there is no creation of new information leads to infinite regress. Indeed, if all I know is what I learned from *A*, who in turn learned it from *B*, and so on, then the only way of putting an end to the chain is to postulate either a Prime Mover or a Platonic realm of eternal ideas, neither of which is a useful and testable hypothesis. Besides, we should recall that, although the environment of mankind has always contained electromagnetic fields, molecules, and cells, it took millions of years of biological and cultural evolution for the emergence of organisms capable of creating the corresponding ideas. In short, information is not out there for grabs: the organism absorbs most of the stimuli impinging upon it, transforms a few of them into processes of other kinds (i.e. transduces them), and generates its own, part of which it transmits to other animals.

2. COGNITIVE FUNCTIONS

2.1. *Perceiving, Thinking, and All That*

We get to know about the world and ourselves through perception and ideation, two distinct but intimately related neural processes. Perception is the last stage of a process that normally starts as mere detection or sensation in some neurosensor (or neurodetector), such as a nerve ending in the skin or in the tip of the tongue. Sensation is the specific activity of sensory systems such as the olfactory and the auditory systems. The neuroreceptors are quite unlike physical or chemical receptors, in that they are under the constant "downstream" action of the central nervous system. Consequently the state of a sensory system depends on the state and history of the brain as well as on the nature and intensity of the stimulation. Hence we are unlikely ever to sense the same stimulus twice in exactly the same manner. Yet we may perceive the two stimuli as identical even if they are not. Moreover we may miss a tone or a motion altogether unless we were expecting it. (See Figure 1.5.) To put it into other words: the response is a function of both stimulus and internal state of the organism. (When Hunter said this in 1929 he was not listened to: the behaviorists were prepared to hear only results fitting the stimulus-response model, which ignores the state of the organism.)

In the higher vertebrates sensation is processed in the sensory cortical "area", which is divided into the primary, secondary, and tertiary "areas". The primary "area" is a component of the corresponding sensory system, and apparently it is particularly malleable during the early stages of development, which is when the animal learns to smell, see, hear, etc. We shall assume (Hebb, 1966; Bindra, 1976) that, whereas sensation is the specific activity of a sensory system including the primary sensory cortical "area", perception is this activity together with the specific activity of the plastic neural systems directly attached to it, i.e. the secondary and tertiary

"areas", as well as whatever other plastic neural systems may be activated by them. Thus there is a long neural way between odor (or light or sound or pressure) reception and its perception, i.e. smelling (or seeing, hearing, or feeling).

Far from being isolated from other neural activities, perception is linked with a number of them, including ideation and behavior. (See Figure 1.6.) This link accounts for the fact that perception can occur in the presence of fragmented stimuli, on the basis of minimal cues, and even in the absence of sensory stimulation. It also accounts for the various constancies (of, e.g. distances and shapes) as well as for spontaneous perceptual processes such as hallucinations and those involved in dreams. This view is at variance with the causal theory of perception, according to which every percept is caused by an external thing, and this in an invariable manner. This view, which is still going strong, ignores the ongoing spontaneous activity of the brain as well as the complexity of the processing of signals coming from the sensors. Perceiving is never a passive effect of the thing perceived: it is not copying·but constructing (Neisser, 1967; Bindra, 1976), and therefore it is midway between sensing and thinking (Gregory, 1970). When perceiving something we construct a percept of it with sensations, memories, and expectations.

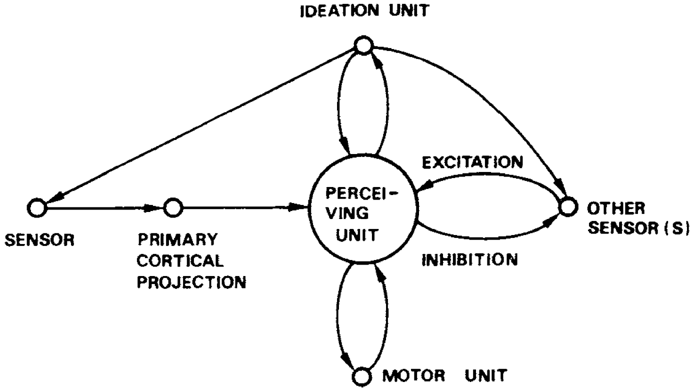

Fig. 1.6. Perception is linked to sensation, ideation, and behavior. Schema inspired by Bindra (1976), who in turn modified it from Hebb (1949).

In other words, the stimuli coming from the perceived object elicit *changes in the ongoing activity* of the nervous system rather than causing the latter. (This is why we assume that an animal perceives an external object as the symmetric difference between the activity of the corresponding process in the presence of the object, and in the absence of it: see Bunge, 1980a, Postulate 4.1.) Therefore there can be perception without external stimuli, as in hallucinating and dreaming, but not without a perceptual system. It follows that there can be no extrasensory perception (ESP). And if there is no ESP (clairvoyance, telepathy, precognition, and the like), then parapsychology is an illusion (Wundt, 1879; Hansel, 1980). What remains to be explained is not the alleged facts of parapsychology but the gullibility of parapsychologists—a task for social psychologists (Alcock, 1981).

Strictly speaking we do not perceive things but events (changes) occurring in things. Thus we cannot see an object unless it emits or reflects photons of a certain energy. Moreover some such events, to be perceptible, must trigger processes ending up in some neurosensor or other. Unless the two conditions are jointly satisfied the object remains invisible. And the way the animal perceives the events occurring in its neurosensors is by *mapping* them into events in some of its perceptual systems. Admittedly this mapping is partial (not everything gets represented) as well as distorted. Nevertheless it is a genuine map, i.e. a representation of certain sets (of events) into another set (of events). The first set (or domain of the function) is a collection of events in the environment or the periphery of the animal, the second set (or codomain) is a collection of events in the perceptual

$$\begin{tikzcd}

 & & 2^{E(c)} & \text{PERCEPTUAL EVENTS}
\end{tikzcd}$$

Fig. 1.7. Events in the environment e of animal b are projected into pairs ⟨bodily state, set of bodily events⟩. This map dovetails with the next, or somatosensory map, which projects external events into cortical events, or points in the secondary or tertiary sensory area. The composition of the two maps yields the external world map for the corresponding sensory system. $E(e)$ is the set of possible events in the environment of the animal; $S(b)$ the state space of the animal and $E(b) \subset S(b) \times S(b)$ its events space. $2^{E(b)}$ is the family of all subsets of $E(b)$; $2^{E(c)}$ is the family of all subsets of the event space $E(c)$ of the cortical system concerned. Details in Bunge (1980a).

system of the animal. In every case the map or function depends not only upon the sensed stimuli but also upon the state of the animal. See Figure 1.7. Maps or internal representations of this kind allow the animal to "navigate" in its environment.

Whereas some memories are remembered, others are forgotten, temporarily or permanently. And those that are recalled are so, more often than not, in a distorted way: like perceiving, memorizing is creative—i.e. not just storing and retrieving but reconstructing (Bartlett, 1932). Donald Hebb used to ask his students to remember breakfast. They all "saw" themselves (with their mind's eye, as we say in ordinary language) sitting at table—an obvious construction. This constructive or creative feature of memory is ignored by the computer (or information-theoretic) metaphor, according to which the learned items are encoded, stored, and then retrieved, possibly with loss, never with gain. This holds literally for computer memories and library systems, but is grossly off the mark in the case of brains.

Since the storage models of memory are inadequate, some dynamical model is likely to prevail. One such model involves the following hypothesis: "Remembering consists in the fresh production or reconstruction of an item, not in the *re*-activation of some permanent representation of the item as such, and what item is remembered—the response production—is the pexgo [psychon] selectively activated at the time of remembering" (Bindra, 1976, p. 330). Rather than permanent changes in circuitry, there may be a propensity or disposition for certain neural systems to be activated, either spontaneously or induced by others. Such dispositions may be quantitated as the probabilities of certain synaptic connections. Any such probability increases with use and decreases with disuse or abuse (e.g. drugs), or just age. The ability to memorize is of course necessary for learning anything: patients who have lost their short term memory (as a result e.g. of brain injury) are incapable of learning anything but for some elementary behavior patterns. (Amnesic patients can be conditioned even though they fail to remember the conditioning process: Weiskrantz and Warrington (1979).)

Of all the brain functions thought is the most remarkable and the least understood. Forming concepts, transforming and interrelating them to construct propositions, questions and directions, are examples of thinking. (Many psychologists include visual images among thoughts—but then why not auditory, olfactory, and tactual images? We regard visual imagination as perception in the absence of sensory stimulation, and submit that it can help or hinder thinking, not however take its place.) Let us deal quickly with the formation of concepts and propositions.

One of the characteristics of the formation of concepts, as well as of the production of the corresponding verbal expressions, is that they may occur in the absence of external stimulation: they can be purely internal processes without sensory inputs or behavioral (motor) outputs. And, when elicited by external stimuli, concept formation (and the corresponding speech production) may involve lack of discrimination. Thus we can form the general concept of a tree perhaps because we possess plastic neural systems the specific function or activity of which is roughly the same whether they are activated by seeing or remembering a maple tree, a fir tree, or a birch tree: such psychons are generalists rather than specialists (Bunge, 1980a). An alternative account of concept formation is this. Every time an animal perceives a tree, several million neurons are excited, perhaps a different set every time. But there may be a thousand neurons common to all those different excitations. These will become organized into a neuron assembly, for neurons that fire together tend to stay together. The activity of this neuron assembly is (identical with) the general idea of a tree (Hebb, 1949). It is up to experiment to determine whether one of these hypotheses, or a third one, is true.

We hypothesize that forming complex concepts, propositions, problems, instructions, and other composite ideas consists either in psychon grouping or in sequential activation of two or more psychons (possibly cortical columns). Thus the concept of an even number would be formed by the pairing of psychons for "number" and for "even". An alternative hypothesis is that such a concept consists in the successive activation of the simple psychons concerned—an extremely fast succession indeed. (In this case language would certainly make a difference for, whereas in English and German 'even' comes before 'number', in the Romance languages it is the other way round.) However, the two hypotheses are mutually compatible. Indeed, psychon pairing may occur during learning (or relearning), whereas sequential activation may happen while using or applying the learned item, since language may be regarded as a vast storehouse of ready-made thinking bricks. The young child has to think hard to add two and three: we just use the result, encoded in a linguistic entity, when needed. (More on language and thought in Ch. 3, Section 3.2.) Once the learning period is over we can perform uncounted mental operations in a thoughtless ("mechanical") manner, just as we walk or drive relying mostly on automatisms. But in either case we may have to resort to new thinking when faced with novelty. (Unfortunately we do not always do so: witness the ideologue who, because he cannot cope with novelty, wants the world to stand still.)

Psychon pairing and sequential activation explain much but not everything. In particular they do not account for our occasional ability to direct thought or "concentrate" it on one task in spite of external (sensory) and internal (spontaneous) excitations that could be diverting. However, the directedness of thought is explained psychologically by the fact that it always occurs in a context: that of the problem at hand (or rather brain), which in turn is embedded in a body of knowledge. In turn, this context has a possible physiological explanation: it could be the background activity of psychons associated with those doing the thinking (Hebb, 1976). And the fact that we are able to restrict the activity to some psychons (rather than engaging the entire plastic brain) can be explained in terms of lateral inhibition, or the containment of the spreading of nervous excitation. To be sure all this is speculation, but reasonable and fertile: hypotheses such as these underlie empirical research into the physiology of thinking. (See Bechtereva, 1978; Goddard, 1980.)

In any event we assume that a thought, be it a concept, proposition, inference, problem, or command, is a brain process. More particularly, we postulate that every thought is a specific process occurring in some plastic neural system or psychon of some animal. Hence a thought may be described as the sequence of states of such psychon over the time lapse it takes to be completed. The particularities of such process are likely to vary from individual to individual, and even from moment to moment in one and the same individual. Thus it may well be that nobody undergoes exactly the same brain processes when thinking of the number 5 at different times: it could be that different psychons are activated at different times (Bindra, 1976). However, any such thoughts of the same construct must be equivalent in an important respect, i.e. the processes must have the same general shape, for otherwise they would not consist in thinking of the number 5.

(Suppose neuropsychology discovers the exact nature of such equivalence, and call it $\sim$. Further, call $\theta_{ij} = \pi_s(b_i, \tau_j)$ the specific process occurring in brain b_i, during period τ_j, when thinking of a certain construct. Since all the processes consisting of thinking of the same construct are $\sim$-equivalent, we write: $\theta_{ij} \sim \theta_{mn}$ for all i, j, m, n. We now form the equivalence class (set of all $\sim$-equivalent processes) $[\theta_{ij}]_\sim$. Finally, we identify the construct c with this equivalence class, i.e. we set

$$c = [\theta_{ij}]_\sim.$$

In other words, *a construct is not an individual brain process but an equivalence class of brain processes* occurring in different brains or in the same brain at different times (Bunge, 1981a). As long as the exact nature of the equivalence relation $\sim$ is not defined, this is a programmatic or heuristic hypothesis that can guide the very research into the identification of $\sim$. More on such equivalence in Ch. 2, Section 1.1.)

The psychobiological conception of thinking explains the association of ideas, that mainstay of empiricist psychology and epistemology, as well as its *bête noire*, intellectual creativity. Association is explained as the interconnection of psychons, and originality as the formation of radically new psychons. Neither is mysterious: interconnection because the whole brain is a system, so that anything happening in one of its components influences some other components. (The influence may be positive and may get established, as in the case of association, or it may be negative or inhibiting, as when every time we think of mathematics we tend not to think of sports.) And originality is not mysterious because of the remarkable spontaneity and plasticity of the cortical neurons.

(The ideas of association and of originality may be formalized roughly as follows. Let S_i be the collection of cognitive acts that subject i performs up until a certain time: call it the *cognitive space* of i. Further, call x and y any two members of S_i, and interpret their concatenation $x \circ y$ as "cognitive act

x associates with (or is followed by) cognitive act y". Finally, call 0 the act that does not increase knowledge even if it was intended to do so; more precisely, 0 represents an arbitrary unsuccessful cognitive act—not to be mistaken for $\varnothing$, or total ignorance. We postulate that the structure $\langle S_i, \circ, 0 \rangle$ is a noncommutative monoid. This amounts to the hypothesis that there are no isolated cognitive acts, but any cognitive act may be associated with some other cognitive act. And we may stipulate that a cognitive act is *original* with subject i if, and only if, it belongs in S_i but not in the cognitive space of any other animal up to the given time.)

2.2. *Learning*

Learning can be conceived broadly or narrowly: as adaptation or as neural modification, temporary or permanent. In the former case one may say that an organism which has developed immunity to some antigen has "learned" to face the latter, and even that a population which has become adapted to a changed environmental—after a wasteful selection process—has "learned" to live in it. Although such a broad construal of learning puts it in a biological perspective, it erases the specificity of the individual neural process accompanying the acceptance or generation of new information. (The same charge can be laid against the information processing view.) Therefore we adopt the narrow construal of learning as neural modification.

We assume, then, that an animal *learns* something if it forms at least one new psychon (plastic neural system) or combines in a novel fashion two or more psychons that had been established previously. And we call *knowledge* of an animal at a given time *the set of all the items it has learned* up until that time—i.e. the collection of changes in its plastic neural supersystem. (Such changes need not all consist in permanent alterations of connectivity: some may consist in changes in the probabilities of certain synaptic connections.) Needless to say, accumulating experience (learning) is not passive recording but a process where signals are selected (mostly filtered out) and transformed—distorted and enriched. In short, learning is *creative* even when it consists only in learning what other animals have learned before. It is creative in the sense that it is not automatic and that it is new to the individual.

Like any other brain process, learning can be represented as a change in an abstract space representing the possible (lawful) states of the brain. An animal engaged in a learning process can be said to expand its plastic neural

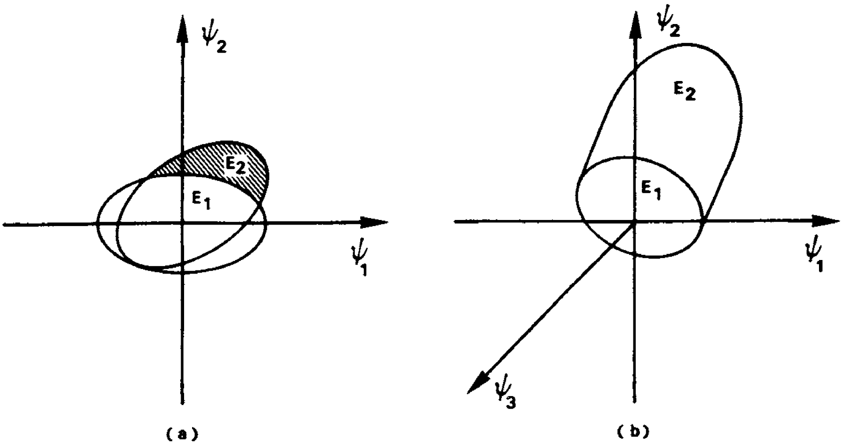

Fig. 1.8. Two kinds of learning. (*a*) Learning of one more item of a given kind (with eventual loss of some experience). (*b*) Learning something qualitatively different is represented by the intervention of a third coordinate axis in the neural state space. Adapted from Bunge (1980a).

state space. This extension can be quantitative or qualitative: the former when the animal learns one more trick of a kind it has sampled before, and the latter when it learns something of a different kind. Thus learning one more word and one more algorithm fall into the first category. On the other hand the learner's neural state space expands qualitatively—i.e. new axes sprout—when it masters a new subject for the first time. The most rewarding aspect of research and advanced teaching is that it encourages the sprouting of new axes in one's brain state space. See Figure 1.8.

Several learning theories are compatible with both the neuroscientific and the psychological data. Only a few of them are deep, i.e. concerned with changes in neural systems, but they are not detailed enough. Most learning theories are purely descriptive: they disregard brain mechanisms and concentrate on the necessary and sufficient environmental conditions for learning. (In particular, the fashionable information-processing view, which ignores the nervous system, is a metaphorical description of what happens during the learning process.) However, some of these theories do capture certain important features of learning, particularly that it is a stochastic process, i.e. a sequence of events every one of which has a definite probability.

Figure 1.9 illustrates the class of stochastic learning theories in the case of single trial learning. The animal is assumed to have probability p of

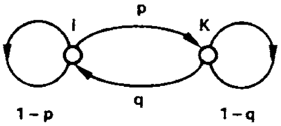

Fig. 1.9. A stochastic model of all-or-none learning events. The arrow from *I* to *K* symbolizes learning, and the converse forgetting. The closed loops represent not learning (left) and not forgetting (right).

learning a given item at a trial, hence probability $1 - p$ of not learning it; and it has probability q of forgetting it, *ergo* $1 - q$ of remembering it. If multiple trials are allowed a well known pattern emerges. For any given task the number of successes increases with practice (i.e. number of trials) as well as with the number of successes. (Successful learning is its own reward.) Likewise the number of errors decreases with practice as well as with the number of errors that get corrected. (Otherwise the process is haphazard, i.e. no trend emerges.) The result is the logistic curve: Figure 1.10. This curve summarizes a purely descriptive theory of learning that does not account for the learning mechanism—let alone its neurophysiological "substrate" or "correlate". It is a datum to be explained by neurophysiology.

Another view of learning that fails to make contact with neurophysiology is innatism, according to which "Learning is primarily a matter of filling in detail within a structure that is innate" (Chomsky, 1975, p. 39). On this view knowledge of a certain kind, i.e. pre-existing—in

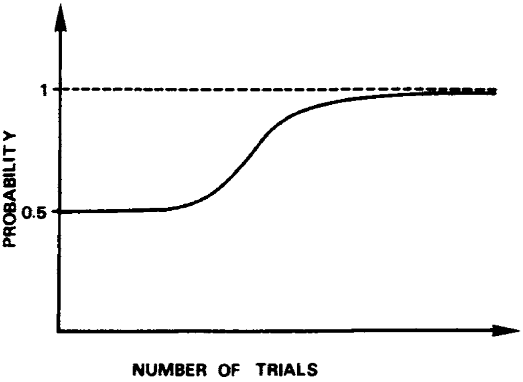

Fig. 1.10. The logistic learning curve: if errors are corrected, the probability of correct performance approaches 1 as the number of trials increases.

particular innate—knowledge, makes learning possible, not the other way round (Chomsky, *op. cit.*, p. 118). Needless to say, there is not the slightest shred of empirical evidence for this speculation. On the contrary, the anatomy, physiology and psychology of development show that the newborn human knows nothing, learns only gradually, and cannot skip any stages because learning keeps pace with the maturation of the nervous system.

The existing learning theories are nonspecific: they are assumed to represent motor learning (e.g. learning to ride a bicycle), perceptual learning (e.g. learning to discern a pattern in an assemblage of dots), conceptual learning (e.g. learning new concepts and propositions), etc. Yet it is obvious that there are big differences among these various kinds of learning, and it is well known that they are done with different subsystems of the brain. Thus conceptual learning, unlike learning of other kinds, involves understanding and it may proceed without any sensory-motor concomitants. So, in addition to general learning theories we need learning models representing each a given type of learning. For example, a model of motor skills learning, even if superficial (i.e. non-neurophysiological), should account for the interplay of behavior and cognition. Thus in the higher vertebrates stimuli that can teach (unlike those that elicit only reactions of the knee jerk type) do not trigger responses automatically but elicit the intervention of cognitive activities such as anticipation and recall.

In other words, the learning process initiated by an environmental stimulus is not summarizable by a stimulus-response arrow. Instead, what happens is that the stimulus is paired to some cognitive state, and both produce jointly a response. (In short, instead of $s \mapsto r$ we have $\langle s, c \rangle \mapsto r$.) In turn, the response has some consequence or outcome (internal or external). If the animal receives information about such outcome, this information may change its cognitive state, producing next time a different response, hence a different outcome, in the presence of the same stimulus. In short,

First trial ⟨stimulus, cognitive state⟩ ↦ response ↦ outcome.

Second trial ⟨stimulus, new cognitive state⟩ ↦ new response ↦ new outcome.

By comparing the successive outcomes the animal may learn whether they converge to the goal or desirable state. If they do not, it may correct the strategy—or give up. This sektch of a feedback learning model can be mathematized, "embodied" in a neural system, and in principle tested both behaviorally and neurophysiologically.

Not only learning theory but most of psychology and the whole of epistemology are attempts to answer the question 'How do we learn?' The empiricist answer is: 'I learn from my own experience and provided my behavior is reinforced (e.g. my ideas are confirmed)'. Skeptics and idealists, on the other hand, deny that we learn from experience—unless perhaps from negative experience, i.e. from mistakes. As is so often the case, each of the contenders holds a grain of truth. We do learn something (not everything) from experience—provided our nervous system is in a receptive condition, we are motivated (and thus willing to make an effort), and the material to be learned is somewhat organized.

That the nervous system must be in a receptive condition is obvious, although this point is ignored by both empiricists and idealists. No matter how well a learning material is presented, a person under the influence of alcohol or some other drug may be unable to learn it. But a healthy brain is not enough, nor is skillful teaching sufficient. Thus whereas Pavlov believed that we can learn automatically from paired experiences (e.g. sound of a bell and temporally contiguous presentation of food), it has been found that repeated paired experiences do not guarantee learning. (See Dickinson and Mackintosh, 1978.) It has been conjectured that, for somebody to learn to do B whenever A happens, he must somehow realize that A and B may be associated (Dawson and Furedy, 1976).

Learning requires also some motivation: an animal without motivation to learn will not explore (Bindra, 1974). Motivation for learning can be *intrinsic* (curiosity) or *extrinsic* (for the sake of a reward other than satisfying curiosity). Hence we can teach ourselves, and others can teach us, to regulate both motivation sources. Thus the standard teaching techniques, by emphasizing extrinsic reward (praise, prize, raise in status, etc.) may inhibit adventurousness and may favor a mercenary attitude towards learning. (Anyone trained to respond primarily to external rewards will say to himself that, since he wants a sticker or some other prize, he should pick problems he knows how to solve safely and quickly rather than problems that will keep him wandering and wondering.) In any event, learning is the easier the more strongly motivated—and motivation is in turn enhanced by learning.

Learning, then, is not just picking up information and processing it in a mechanical way: it is a highly selective and creative process (Piaget's *assimilation*). Nor does the brain remain unaffected by learning: it restructures itself as a result of learning (Piaget's *accommodation*). To be sure an isolated brain would be unable to learn anything; moreover it would not even function normally, as shown by the experiments on sensory deprivation. However, looking, listening, sniffing and touching are not enough to take cognizance of anything beyond appearances. Recall that humans have always reproduced, yet did not discover the reproduction mechanism until a couple of centuries ago; they have presumably been speaking for many thousands of years, yet linguistics was not born until the 19th century; they have always lived in the midst of a gravitational field, but this fact was not discovered until recently; and they have been playing games of chance for millennia, yet the earliest ideas about chance and probability were not conceived until the 17th century. In short, sense experience and action are poor teachers: most people do not learn readily from either. (It is easier to learn to perceive and do.)

This difficulty to learn from sensing and doing has multiple sources: (*a*) appearance, unlike reality, is poorly structured; (*b*) all signals are embedded in noise; (*c*) perception and memory are highly selective: whereas at times they discard details, at other times they pass over essentials; (*d*) motivation is often lacking; (*e*) learning much and fast requires lots of knowing; (*f*) we learn most easily those items that happen to be consistent with our belief system, and tend to ignore those which are dissonant—as is the case with unfavorable evidence for our pet beliefs; (*g*) we are seldom equipped with comprehensive and coherent theories helping us "make sense" of experienced events, so we have nowhere to "file" the latter; (*h*) knowledge need not make us more receptive: learning develops a "set" (*Einstellung*) or habit that makes if difficult for the subject to face new problems or situations; (*i*) we may be insufficiently trained in logic, scientific method, statistics, and experimental design—all of which help learn from experience; (*j*) we may need to appear in the right for social reasons, and may thus be driven to simulate that we have got the message, or that there was no message to be received.

Some philosophers, particularly Popper and his followers, believe that we learn only from our mistakes, i.e. by punishment. Experimental psychology has refuted this view, showing that most people manage to learn a lot and yet they disregard negative evidence and seldom seek it (Wason, 1960; Smedslund, 1963; Jenkins and Ward, 1965; Einhorn and Hogarth, 1978). Consider the following situation. A subject is instructed to take action A if a certain variable X lies below cutoff point X_c, and action B otherwise. Further, his decisions have outcomes of two kinds: success in case a certain variable Y falls below a certain cutoff point Y_c, and failure otherwise. The state space of Figure 1.11 can then be built. Experimental

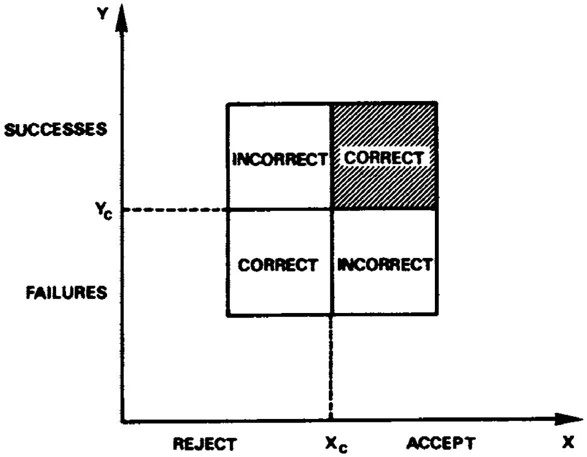

Fig. 1.11. A common fallacy. See text. Adapted from Einhorn and Hogarth (1978, p. 397).

studies (Einhorn and Hogarth, 1978) show that the only feedback most people care about is that coming from the pairs ⟨correct decision, success⟩, i.e. the points in the shaded cell. They generally ignore information in the three other cells, i.e. they tend to disregard the misses—as Bacon noted—and even the correct forecasts of failure (or non-occurrence). In other words, most people do *not* learn from their mistakes or even from their hits unless the latter bring rewards. Only a scientific training may instil the habit of seeking disconfirming information. In other words, ordinary experience is not self-correcting: it only gives us a chance to recognize error and learn to avoid it in future. Only scientific experience is consistently self-correcting.

If we knew more about learning we would not propose simple-minded epistemologies and would be able to learn in more efficient ways. As it is, we must make do with a handful of rules of thumb. One such rule is that *extremes of speed must be avoided in learning*: too slow a pace because it induces boredom, too swift a rhythm because it leaves no time for consolidation. We must regulate the inflow of information to keep it within moderate bounds. It must be quick enough to keep the neural systems alert to novelty: otherwise they become habituated or adapted, i.e. they do not respond. And the flow must not be so quick that psychons are dissolved no sooner they are formed, with the resulting confusion and poor recall. Low speed is best left to invertebrates, and high speed to computers: we had better choose medium speed and concentrate on selectivity, creativity, generality, and depth. Selectivity is becoming more and more important because we are subjected to an incessant bombardment with irrelevant information: we must learn to evaluate and discard or skim most of the information that comes our way if we wish ever to make an original contribution to human knowledge. We must learn, in short, to choose wisely what to learn: "what we all need at this point in human evolution is to learn what it takes to learn what we should learn—and learn it" (Aurelio Peccei).

A second rule for efficient learning is: *Avoid cramming huge piles of unrelated data* ("facts"), for they are difficult to comprehend and recall. We tend to organize the stream of incoming information into "chunks" that can be understood and recalled as units or systems (George A. Miller). Thus coherent stories can be understood and recalled more readily than isolated sentences, and the latter more easily than nonsense syllables. The keys to this are of course connectedness (systemicity) and significance (what signs "say" about what). If this finding of experimental psychology were better known, chemists, biologists, medical researchers, social scientists and others might lower their resistance against theorizing, for theories are systems of knowledge. But of course theories are not data packages and therefore they will never replace data, such as addresses, formulas of chemical compounds, or historical dates. Hence we must learn such items alongside theories—but learning the latter will ease the learning of the former, for theories can be used as filing systems where data can fit.

A third rule to be followed is this: *Don't miss the apprenticeship period and get hold of the best teachers you can.* All animals capable of learning pass through a period of apprenticeship in some skill or other—e.g. flying, singing, fighting, exploring the environment, earning a living and, in the case of primates, even copulating. One does not become a farmer or a master builder, a manager or a research chemist, just by reading books, auditing courses, or watching television programs: every craft is learned at the knee of some master. One reason is that know-how cannot be wholly transmitted except by example. Another is that the text-book and the research paper give condensed and tidy reports on a process that has been anything but brief and tidy. A third reason is the need for incessant feedback (correction and encouragement). Those who object to apprenticeship calling it paternalistic, coercive, or repressive, will never train any disciples except in the arts of barren revolt and misleading rhetoric.

However, stressing the need for apprenticeship should not be mistaken for praising brainwashing, or even for favoring protracted apprenticeships. It is true that humans are remarkably immature at birth, and that they have to learn to cope with a habitat made extraordinarily complex by their forebears. Still, it is questionable whether the current apprenticeship period is wise, the more so since it tends to increase. Doctorates in science are obtained in the West on the average at 29 years of age, i.e. they take 23 years of schooling not counting preschool. The reasons for this long and costly apprenticeship period seem to be to make sure that the candidate (*a*) has mastered the skills of the previous generation—which is unnecessary and impossible anyway; (*b*) will stick to the traditional ways (rather than try radical novelties), and (*c*) will stay out of the market place, thus protecting his teachers and himself. The apprenticeship should not be so short as to leave the student ill prepared to face professional problems by himself; but it should not be so long as to dry up every innovative and rebellious impulse. We should start earlier and be more demanding; but we should demand less curricular uniformity, cram less stray data, and allow more freedom of search and criticism.

Finally, are there limits to what an individual can learn? Is every one of us, as information processing psychology claims, a limited capacity information processor subject to Shannon's law concerning the limited capacity of every channel (Miller, 1967)? The limited capacity thesis applies to telephone lines, computers, and other artificial information systems, but it has not been proved for humans. There are indications that it does not apply to our brains: (*a*) unlike artificial information processors, our brains are plastic and, in particular, they have the property of self-organizability; (*b*) every time we learn something we become better prepared to learn further items: learning is an autocatalytic process, not the filling of prefabricated book shelves; (*c*) with practice we can learn to do two or more tasks at once—e.g. driving and chatting, typing and listening to music (cf. Neisser, 1980). Of course there are limits, some biological (e.g. poor genetic endowment, loss of neural plasticity, short life span) and others social (e.g. poor cultural environment, few opportunities). But these limits are not fixed once and for all: our brains and societies are to a large extent self-made. We can push the limits to what we can learn by building a society where everybody can freely exert the right to learn. We shall return to this theme in Ch. 13, Section 4.

3. Development and evolution

3.1. *Cognitive development*

Organisms develop from birth and biopopulations evolve over time. Hence there are three different though mutually complementary ways of studying biofunctions, in particular cognitive abilities: synchronically, developmentally, and historically. The synchronic approach attempts to learn what and how an animal learns; the developmental studies the growth and decline of cognitive abilities: how they are formed at an early age, what sequences they constitute, etc.; and the historical or evolutionary approach studies the origin and subsequent evolution of cognitive functions. Clearly, the synchronic study must initially precede all others, for it is impossible to discover the development or the evolution of X unless one has some idea of what X is. But once one has learned something about the development or evolution of X, one can form a better idea of what X is—if only because X has developed and evolved from some predecessor that shares some properties.

All the components of our body are genetically programmed, but they are fashioned, within the genic constraints, by the way we live and in particular the things we do. This holds for the muscles: compare those of an athlete and a sedentary professor, or a beef eater and a tortilla eater. And it holds for the brain, as the neurons of the plastic components of the brain can sprout dendrites and make synaptic connections all the time—or lose them with disuse or age. The brain, like the muscles, develops the way it is nourished and used. Thus our entire body is to a large extent self-constructed—particularly so the brain, which ultimately selects what food and what information it is to feed on. We are born with the ability to form new neural assemblies or psychons, but which ones will be formed depends on both internal and environmental circumstances. A severe protein deficiency in infancy may result in low intelligence, and repeated exposures to antisocial behavior may ensue in the same. The genome determines only the potential: which potentialities are actualized depends on the way the psychons develop, and this development is molded by both the natural and the social environments.

The brain of the neonate is immature: it weighs only one-fourth of the adult brain, and its cortex performs few specific functions. In particular its cortical neurons are small, have few and short dendrites, and are hardly interconnected. No wonder the newborn human is slow, clumsy, mindless, and therefore helpless. As the child grows up its neurons grow, sprout dendrites, and make synaptic contacts with neighbors. What began looking as a sparsely populated forest ends up by looking like a tangled jungle: see Figure 1.12. The maturation process continues throughout life unless senility sets in.

The maturation of the brain is a process composed of five main threads:

V
VI

Fig. 1.12 Sections of the same region of the cerebral cortex of a newly born human (left) and of a 7 year old. From Conel (1939/67).

(*a*) growth of neurons; (*b*) growth of the myelin sheaths that wrap up and insulate the neuron axons; (*c*) change in the chemical composition of the neurons and the synaptic clefts; (*d*) proliferation of dendrites, and (*e*) multiplication of possible contacts with neighboring neurons, and thus formation of new psychons. Whereas processes (*a*) and (*b*) are completed in a few years, the others seem to go on for life. The maturation process is not homogeneous; in particular, the various cortical "areas" mature at different rates. Thus the motor "areas", which are partly prewired at birth, mature earliest; then come the sensory "areas", and in the first place the visual one. It is estimated that the cortex does not become fully functional until around 20 years of age. And it is known that the connectivity or interneuronal linkage remains changeable throughout life—barring senility. As the maturation process proceeds, new abilities emerge whereas others are lost. Thus it is likely that every one of Piaget's stages is the manifestation of the attainment of maturity (full functionality) of a large neuronal system.

The development of the nervous system can be somewhat accelerated by favorable environmental circumstances, and it can be distorted or even arrested altogether by unfavorable ones. For example, a kitten allowed to use a single eye during its first year of life will fail to develop binocular vision even after having been allowed to use both eyes (Wiesel and Hubel, 1965). A monkey shown only vertical lines in infancy will be unable to perceive horizontal bars later in life. A child who is not spoken to until age three may never learn to speak properly. In short, if the proper interneuron connections are not made in time, they are never made. In particular, certain cognitive abilities are not acquired or developed if the sensitive or critical period is missed. Practical consequence: Expose children and youngsters to rich and variable environments, and give them a chance to learn skills as early as possible. *Early training* is the ticket.

Developmental neuroscience and psychology, though still in their infancy, are in a position to solve the old nature/nurture (or nativism/empiricism) controversy, i.e. the question whether our cognitive abilities are inherited or learned. (The current dispute over the inheritability of intelligence is of course part of that controversy.) However, before rushing to take sides, or to propose a third alternative, we should clarify the rather vague notion of innateness.

According to contemporary biology "innate" subsumes two different concepts: "inborn" and "inherited though not present at birth". An inborn trait is one possessed at birth, such as the capacity to breath, move, cry, look, or listen to spoken words in the case of human infants. Most inborn traits are inherited but some are outcomes of genic changes (e.g. mutations) or of original embryogenic processes. An inherited trait is one handed down by the animal's ancestors through the DNA molecules contained in the germ cells. Not all inherited traits are inborn; many emerge (or are "expressed") during development until the adult stage is reached. And, whether present at birth (inborn) or expressed later on (inherited), every such trait is ultimately controlled by the hereditary equipment (genome). In particular, an innate (inborn or inherited) cognitive function is one performed by a genetically programmed system. Thus "Animal *A* possesses innate capacity *B*" is spelled out "Animal *A* possesses neural system *C* which, when activated, discharges function *B*".

Now, like any other material system, from atom to society, a neural system has properties of two kinds: actual and potential. I.e. there are some "things" it does and others that it may do. Thus an atom is always moving relative to some thing or other (actual property), and it has the possibility of being excited by incoming radiation of certain wavelengths or, if already in an excited state, of decaying to some lower energy level. Likewise a neural system has, in addition to some permanent properties, others it can acquire, such as learning to perform certain functions. Indeed, whereas some neural systems are prewired (or develop into rigidly wired systems), others are plastic, i.e. they are formed, strengthened, or weakened in the course of life. (Recall Section 1.1.) Thus an infant starts learning the moment it is born: this shows that the ability to learn certain skills is inborn. On the other hand, in order to learn other skills the animal must wait for its nervous system to mature, and for the environment to offer the opportunity. However, this opportunity may never arrive, particularly in conditions of extreme biological and cultural deprivation. Suffice it to recall that children raised with insufficient food, parental care, perceptual and mental stimulation, and interaction with their peers, do not develop a normal brain: they can seldom if ever become intelligent.

In the light of the preceding we realize that nativism and empiricism, the psychological trends dealing with the nature/nurture controversy, are mutually complementary rather than exclusive (Dodwell, 1975)—and yet they are not exhaustive because neither acknowledges creativity. The reason both are needed is that, in the light of psychobiology, each is concerned with a certain kind of neural system. Nativism is (tacitly or explicitly) concerned with wired-in or rigid connections, which are typically innate (either inborn or formed later under the control of the genome). On the other hand empiricism is (tacitly or explicitly) concerned with plastic or variable connections, which are typically acquired (learned).

Since the brain of a higher vertebrate (mammal or bird) contains systems of both kinds, we need empiricism as well as nativism—or rather a merger of the two enriched with the hypothesis of creativity, or the capacity of learning beyond experience. Only such a doctrine could account for the fact that we are born with a central nervous system that is partly rigid (prewired or programmed) and partly plastic (acquired or learned). But this is not all: although our plastic neural systems are partly self-constructed (by learning) they also have inherited capacities. Just as no two animals have exactly the same set of proteins—hence exactly the same chemical reactions—so no two animals are likely to have exactly the same neural systems and therefore exactly the same cognitive abilities. Such inherited neural differences, together with differences in environment and formal education, explain why some children are better than others at games or at languages, at mathematics or at drawing.

(A recent review of 111 studies published in the world literature, and covering 113,942 pairings, confirms the so-called polygenic inheritance of intelligence hypothesis, according to which the higher the fraction of genes two family members have in common, the higher the average correlation between their IQ's (Bouchard and McGue, 1981). However, the data exhibit also strong environmental influences. Thus whereas the average correlation between monozygotic ("identical") twins reared together is 0.86, that of monozygotic twins reared apart is 0.72; the corresponding figures for siblings reared together and apart are 0.47 and 0.24 respectively. Surprisingly, the figures for nonbiological sibling pairs are: 0.29 for adopted–natural pairs, and 0.34 for adopted–adopted pairs. Also, there is no evidence for the role of sex on general cognitive development. Finally, according to another study (Loehlin and Nichols, 1976), "identical" twins correlate only about 0.20 higher than fraternal twins in personality traits.)

In sum, the nature/nurture disjunction is not exclusive: genes determine only potentialities that are actualized or thwarted by the environment. What about innate ideas: are there any? Was Socrates right in holding that there is only remembrance, not acquisition of new knowledge? Before discussing this matter we should clarify the meaning of "idea", the more so since in the philosophical literature instincts and perceptions have sometimes been lumped together with images and abstract ideas. For the sake of precision we shall restrict ideas to concepts (e.g. "wet") and propositions (e.g. "The ground is wet."). The problem can now be restated as follows:

Are any concepts or propositions inborn or inherited? Innatism replies in the affirmative, empiricism in the negative. This 17th century debate has been reactivated in recent times in connection with the psycholinguistic problem of language acquisition—of which more in Ch. 3, Section 3.2.

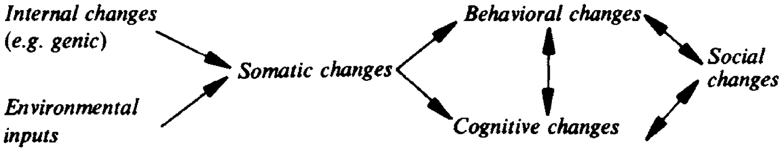
The controversy about innate ideas is bound to remain unresolved as long as it is conducted on the superficial level of traditional mentalistic psychology. Neuropsychology (or psychobiology) is in a position to make a decisive contribution by suggesting that we study the language cortex and its function from birth to school age. We still know very little about this subject: psycholinguists seem to have been busier speculating and polemicizing than studying the child's brain and social environment. However, we do know this much: (*a*) ideation is an activity of fairly large neuron assemblies (psychons), not of germ cells, let alone of their DNA content, which is the only thing that gets transmitted from one generation to the next; (*b*) the brain of the newborn is so poorly organized (recall Figure 1.12) that it cannot even coordinate its movements, so that it is unlikely that it can form any concepts or propositions; (*c*) development is not merely the unpacking or "expression" of genic destiny: it is a creative process punctuated by the emergence of new functions and the exercise of some such functions in the acquisition of new knowledge; (*d*) children who grow up in culturally deprived environments have poor sensory-motor skills and a very poor inner life: although ideation is a brain function, it is not discharged in a social vacuum. In sum, we do not inherit knowledge but only the ability to acquire it in appropriate biological and social conditions. Which is just as well, for otherwise we would be lacking in curiosity, we would get stuck with ineradicable errors along with genetic defects, and the advancement of knowledge would have ceased long ago.

None of this entails that the newborn's brain is a clean slate ready to accept any inscriptions. On the contrary, it is partly a plastic brain with definite potentialities: it inherits not only certain rigid circuits (in charge of the basic household functions), but also the capacity to form new ones, as well as of dismantling some of them. Moreover we can form some such neural systems at will, as when we decide to learn a new motor skill, a new language, or a new branch of knowledge. In sum, we are unlikely to be born with any ideas, but we are born with the possibility of learning and even creating new ideas. (Maudsley (1876, p. 278) wrote that the notion of an innate idea is as absurd as that of innate pregnancy.) Shorter: although we are born ignorant we possess the neural apparatus to learn and, given the chance, we do learn quickly almost anything. Of course there are individual differences traceable to genic differences: some people learn music, philosophy, or engineering, more easily than others. But this is beside the point: the point is that all such skills must be learned.

We share the instinct to learn with numerous animal species. However, we have a definite advantage over them, namely that of being born into a culture built by our ancestors. This inheritance spares us the need to make a fresh start in every single respect no sooner we learn to walk. (One's school record does not recapitulate the history of mankind.) But every cultural inheritance is ambivalent: it assuages one man's thirst for knowledge and incites another's exploration of new territory. Besides, whereas some societies encourage learning, others inhibit it, or at least they discourage inquiring into certain subjects. This being so, we will not learn much about learning if we restrict our inquiry to individual brains: we must study also the social matrix of the learner. More on this in Ch. 3, Section 2.

3.2 *Cognitive Evolution*

The evolution of cognitive abilities is an aspect of biological evolution and social history. All evolution proceeds by internal (in particular genic) variation and environmental (natural or social) pressure. Both factors may be pictured as inputs on the organism. In the case of animals the outputs of such externally induced or modulated changes are modifications of various kinds. Two such kinds of change are of paramount importance for the student of cognition: behavior (in the narrow sense of outcome of muscular activity) and cognition. These outputs are interdependent: new motor capabilities open up new possibilities of perception and ideation, and conversely. And both outcomes, the behavioral and the cognitive, are molded by society and in turn contribute to molding the latter.



The study of the evolution of cognitive abilities is of course one of the tasks of evolutionary psychology. Unfortunately the latter is still underdeveloped to the point of being almost exclusively speculative. There are two main factors of underdevelopment. One is the scarcity of data, almost all of which consist in circumstantial evidence. The other obstacle to the progress of evolutionary psychology is psychoneural dualism: by detaching mind (or "software") from brain (or "hardware"), one forgets that what behaves or ideates is always some animal or other, and that animals happen to be subject to evolution. Nevertheless palaeoanthropologists and primatologists are beginning to learn a good deal about the evolution of the cognitive abilities of our ancestors over a time period of nearly three million years. (See Jerison, 1973; Masterton *et al.*, 1976a, b.) Such problems and findings should be of interest to all biologically oriented psychologists. By the same token they are a matter of indifference to mentalist psychologists, in particular those of the information processing variety, who claim to study either immaterial (disembodied) minds or computer programs, neither of which are subject to organic evolution.

Evolutionary psychology, then, is an underdeveloped branch of evolutionary biology. However, we cannot treat the evolution of the higher vertebrates in the same manner as that of the lower vertebrates, let alone that of invertebrates. Indeed the search for knowledge and possession of it modifies behavior, and behavior is not only an outcome of evolution but also a motor of it (Piaget, 1976b). In other words, by generating and using new knowledge the higher vertebrates can improve their survival strategies and thus modify the direction and pace of their own evolution. This being so, it is not true that for them, as for the lower animals, all variation is blind, and selection the only source of fitness—as assumed, e.g. by Campbell (1977). To some extent mammals and birds can control variations in themselves as well as in their environment, thereby improving their own fitness. Still, this does not entail that higher vertebrate (and particularly human) evolution is Lamarckian rather than Darwinian (as claimed by Piaget (1976b)). DNA, which is what we inherit, does not learn from experience. (For further criticisms see Bunge (1981a).)

A number of thinkers, notably Spencer, Helmholtz, Peirce, Mach, and Popper, have drawn a parallel between the history of ideas and biological evolution: in both cases there would be problems, trials and errors, and only the useful or adaptive novelties would "survive". This analogy passes sometimes for evolutionary epistemology, but it is not. To begin with it is a metaphor, not a theory. Secondly, it is a superficial analogy for, unlike organisms, ideas are neither alive nor self-existent, hence they do not evolve by themselves. New knowledge is not gained by random mutation, and scientific and technological knowledge is seldom gained by blind trial and error. Most new knowledge is obtained by inquiry, and there is no such search unless the animal is motivated (by need or by curiosity) and unless it knows some search strategies, however primitive.

A third objection to what passes for evolutionary epistemology among philosophers is that it is false that the evolution of knowledge consists simply in the elimination of "unfit" hypotheses, i.e. conjectures that fail to pass empirical tests. There is more to knowledge than hypotheses: there are also data and problems, viewpoints and methods, rules and instruments, designs and plans, etc. Fourthly, some patently false superstitions minted thousands of years ago—e.g. the doctrine that ideas dwell in a world of their own—are still going strong, whereas a number of scientific truths and useful technological innovations lie buried in the specialized literature, where they are likely to remain unless independently rediscovered or reinvented. Fifthly, truth does not always prevail once discovered or invented. It is sometimes suppressed for being incompatible with received dogma or vested interest, and at other times it is forgotten for lack of interest.

In short, most of what passes for evolutionary epistemology among philosophers is as removed from biology as it is from the history of knowledge. (For further criticisms see Currie (1978).) Genuine evolutionary epistemology takes organic evolution seriously, deals with the evolution of cognitive abilities as an aspect of brain evolution, and takes the social matrix into account. (For a sketch see Vollmer (1975).) True, evolutionary epistemology is so far little more than a research plan, so the philosopher cannot learn much from it. However, he should adopt a genuine evolutionary viewpoint, which involves dealing with concrete organisms immersed in concrete environments, rather than with disembodied minds (or computer programs) hanging in a natural and social vacuum.

4. CONCLUDING REMARKS

It is legitimate to *distinguish* knowledge from the cognitive process. But it is impossible to *separate* them or to try to understand the one without the other—as impossible as to understand ashes without fire. Philosophy may well leave the detailed study of cognition to the cognitive sciences, but it cannot ignore them, and it must make such studies the firm (though changing) root of epistemology. It can disregard them only at the risk of producing obsolete and barren armchair psychology.

There are several approaches to cognition. One is to treat it as a particular kind of behavior, and to describe the latter in terms of stimuli and responses. We reject this, the behaviorist approach, because it ignores that which does the cognition, namely the nervous system, and it does not even pose the problem of accounting for intelligent behavior. A second approach consists in begging the question: in taking ideas for granted and trying to account everything else in terms of them. We reject this, the mentalist approach, for being superficial and nonscientific: it fails to explain the nature of ideas, it assumes that they are self-existent, and it ignores the brain, thus isolating psychology and epistemology from all the other sciences. A third approach to cognition is the information processing one, i.e. cognitivism, which does not distinguish between brains and computers, is interested in the processing of information but not in its creation, and identifies body with hardware and mind with software. We reject this approach as well for failing to explain how information is generated and how knowledge guides (or misguides) behavior; it ignores the peculiarities of the nervous system (which it views as one more information processing system), as well as development and evolution, and it presupposes and therefore encourages psychophysical dualism.

The fourth approach to cognition is the *biosociological* one, the basic thesis of which is that every cognitive activity is a neural process, and one that interacts vigorously with other processes in the animal as well as with its natural and social environment. We adopt this approach for the following reasons (Bunge, 1980a, 1981a). First, the biosociological approach to cognition is in harmony with the ontology (or world view) of science, which is one of lawfully changing things rather than one of immaterial entities or disembodied processes. Second, it jibes with the life sciences, in particular (*a*) developmental and evolutionary psychology, which teach us that organisms change considerably in the course of their lives, and biopopulations may change to the point of speciation or extinction, and (*b*) neuroscience, which among other things can explain how the nervous system perceives, imagines, feels, thinks, etc.—or fails to discharge satisfactorily any such functions. Third, the biosociological approach to cognition harmonizes with the social sciences, in particular the sociology of knowledge, which shows that society molds the way we see the world and ourselves, and studies the ways in which society encourages or discourages inquiry, and benefits or suffers from its results.

CHAPTER 2

KNOWLEDGE

We may distinguish knowledge from the process of its acquisition: we may think of knowledge as a product or outcome of cognitive operations such as perception and inference. But of course there is no outcome detachable from process: the former is just the final phase of a sequence of events. Nor is knowledge the invariable outcome of a cognitive process: sometimes inquiry ends up in ignorance, at best in the resolve to engage in further inquiry. In any event knowledge, when acquired, is a collection of learned items: it is a collection of brain processes or a disposition to replay them. Yet although we cannot detach the outcome (knowledge) from the corresponding process (cognition), we may distinguish them.

Moreover for some purposes we may *feign* that cognitive processes have a "content" that can be communicated to other brains or externalized as artifacts such as inscriptions and tapes. To be sure actually there is no such content and, a fortiori, no such transfer. Acquiring knowledge is learning something, i.e. going through a certain brain process, hence not the same as acquiring a book or some other commodity. Likewise exchanging information is not like trading things but is interacting with another animal in such a way that each party elicits certain learning processes in the other's brain.

Yet from a methodological point of view it is convenient to feign that cognitive processes do have a transferable content, so that we may think of the latter separately from the former. This convenient fiction amounts to supposing that, for certain purposes—such as checking validity or usefulness—it does not matter what or who went through the cognitive process in question. It could have been Archimedes in Syracuse two millennia ago, or Einstein in Bern at the beginning of our century. This distinction between cognition and its content is useful in epistemology and there is no harm in it as long as it be understood as a fiction, not as an ontological thesis on the autonomy of ideas (Bunge, 1981a). After all, mathematics too deals with fictions—though not wild or idle ones—and this does not detract from its usefulness. On the contrary, the distinction guarantees impersonality and facilitates universality.

We shall also distinguish knowledge from belief, but this distinction is not a mere methodological gimmick. That knowledge is not belief should be clear from reflection on cases such as "*A* knows *B* but does not believe *B*", and "*A* believes *B* although he does not really know *B*". Yet there is a large body of philosophical literature that defines knowledge as a kind of belief; we shall pay hardly any attention to it.

Finally we shall sketch the features of the deliberate and systematic acquisition of knowledge through inquiry, leaving its detailed study to later chapters. And we shall characterize a field of inquiry in terms of a material framework and a conceptual one.

1. FROM COGNITION TO KNOWLEDGE

1.1. *Knowledge Acquisition and Use*

We have assumed that every cognitive activity is the activity of some plastic neural system or psychon (Ch. 1, Section 2). We must now distinguish between acquiring (learning) a piece of knowledge and using it (e.g. recalling it or putting it into practice). From our neuropsychological point of view this distinction amounts to distinguishing the *original formation* of new psychons (or psychons of new types) from the *activation* of existing psychons (or the formation of psychons of a type that already had representatives in the individual's brain). In other words, we distinguish between the assembly of new neural systems (or circuit rewiring, in the old metaphor) and the use of existing ones. Presumably the lower animals can do only the latter: they do not self-assemble or self-organize new neural systems, except perhaps through malfunction. But we do it as long as we learn new items.

Example 1: An animal is in the process of learning to pair stimuli of kind E to responses of kind R, each accompanied by internal states belonging to the brain state space S. (For the notion of a state space see Ch. 1, Section 1.2.) That is, the brain of the animal is establishing a new psychon "embodying" (represented by) a state function of type $F{:}E \times S \rightarrow R \times S$. Note that this is a very strong assumption, for it implies that a finite number of stimuli can elicit the emergence of a property represented by a function F from $E \times S$, which may contain infinitely many elements, to $R \times S$, which may also be composed of infinitely many members. Clearly, this conjecture goes against the grain of inductivism, which demands that we learn item by item and synthesize only at the end. (More in Ch. 5, Section 2.1.) And the hypothesis is equally alien to innatism: in fact it is an alternative to both rationalism and empiricism.

Example 2: The animal has already acquired the function F in the former example, and so it has acquired the *disposition* to make responses of type R every time it receives stimuli of type E. It is now subjected to a stimulus of this kind (though possibly different from any of the individual stimuli that induced its learning F), and it generates both the suitable response and the accompanying inner state. It is making use of a bit of knowledge acquired earlier, namely the one summarized by the function F.

To give some precision to the preceding ideas we introduce a certain notion of functional equivalence. We say that the linear functions $y = x$ and $y = ax + b$ are equivalent, or belong to the equivalence class of linear functions. Likewise the trigonometric functions $y = \sin x$ and $y = \sin (ax + b)$ will be said to belong to the equivalence class of sine functions. In general, we say that two functions differing only by a linear transformation of their independent variable(s) are *equivalent*. And we write $[F]$ for the *equivalence class of F*, i.e. the set of all functions equivalent to F. We also say that, if the state functions of two concrete (material) systems are equivalent, then the systems themselves and their activities (i.e. the processes occurring in them) are *functionally equivalent* no matter how much they may differ in details.

We are now ready for our definitions of knowledge acquisition and use. Let b be an animal endowed with a plastic neural supersystem P, and consider a time interval τ. We stipulate that

(i) *b acquires knowledge of kind* $[F]$ over period τ if and only if a new psychon, characterized by a state function F (a member of $[F]$), is formed in P in the course of τ;

(ii) *b makes use of knowledge of kind* $[F]$ over period τ if and only if the P of b contains at least one psychon, active during τ, characterized by a state function of kind $[F]$ at the beginning of τ;

(iii) the *total knowledge* of b at time t is the union of all the bits of knowledge, of all types, that b has acquired up until t. We call this set $K(b,t)$.

Note that, contrary to the behaviorist tradition, but in consonance with cognitivism, we have equated learning with the acquisition of knowledge (see, e.g. Dickinson, 1980). However, in contrast to mentalistic cognitivism, we equate in turn the acquisition of knowledge with a partial restructuring of the nervous system rather than with the formation of a new immaterial mental configuration. Our hypothesis is more precise and therefore better testable than the mentalistic one, which contains the essentially vague notion of a mental configuration. Moreover our hypothesis has recently received a sensational experimental confirmation from the study of bird song. In fact, it has been found that in the spring, when male canaries learn new song repertoires, their song control neural nuclei nearly double in volume relative to the fall, when they stop singing (Nottebohm, 1981). This seems to indicate that learning is (identical with) the growth of new dendritic segments and the consequent formation of new synapses, whereas forgetting is the shedding of synapses.

Note also that our definition allows for considerable variability among individuals, and even in the course of the lifetime of any given individual. Thus even if two individuals learn "the same thing" (e.g. to shake hands, or to read graphs), there may be considerable differences in the details of their learning processes. Consequently there may be differences in the outcomes or performances, e.g. in the way they shake hands or read graphs. Second and more important, learning is not done by the mythical hollow organism of behaviorism or by the mythical disembodied mind of the mentalist: learning consists in some nervous system acquiring new properties. (Other organs, such as the heart and the kidney, do not have this capacity: they have fixed state functions.) Third, there is no instantaneous learning, hence no instant knowledge: getting to know anything takes time, however short.

Our definitions have a number of consequences, some of which are irrelevant to traditional epistemology whereas others are incompatible with it. Here are some of them:

(i) An animal lacking any plastic neural systems does not know anything. (Thus a worm has no more knowledge than a stone. When it learns to withdraw from a noxious stimulus, all it does is to inhibit or block certain neural pathways: it does not create any new ones.)

(ii) An animal whose plastic neural system fails to contain a subsystem characterizable by a state function of kind $[F]$, and active during τ, has no knowledge of kind $[F]$ during τ. (Inactivity may be due to sleep or coma, or it may be caused by drugs.)

(iii) All cognitive deficits and abnormalities are dysfunctions, temporary or permanent, of the corresponding neural systems. (Such dysfunctions may occur at the molecular level, as is the case with excesses or deficiencies of neurotransmitters, or at the cellular level, as is the case with "wrong" synaptic connections.)

Acquiring knowledge and using it are cognitive activities, but not every cognitive activity is successful: we may conduct an investigation without learning anything. In other words, the collection of learning activities is properly included in that of cognitive activities. Consider the collection of all the learning activities of an animal b up until time t, i.e. the total knowledge $K(b, t)$ of b until t. We obtain the knowledge of the species to which b belongs by forming the union of all the individuals' knowledge of the species. Thus what we call *human knowledge* at a given moment is the union of all the bits of knowledge—correct or incorrect—acquired by members of the human species up until that moment, i.e. $K(H,t) = \bigcup_{b\in H} K(b,t)$. This is a large collection, for it includes every truth, half truth, and error that every single human has ever learned. We risk nothing by postulating that nobody will ever learn all of human knowledge. Which is just as well, for much of it is not worth acquiring anyway.

For most of prehistory knowledge existed only in individual brains. With the invention of drawing, painting, sculpting, and particularly writing, knowledge could be encoded and externalized in *cultural artifacts* that could circulate throughout the community. This facilitated the storing, sharing, and enriching of knowledge. But it also fostered the myth of the independent "content" of knowledge—independent, that is, from the inquiring subject.

It is easy to see how this myth can be generated and maintained. When somebody finishes a paper or a drawing, these pieces of matter can be detached and seen by somebody else: even their creator can stand back and contemplate them as if they were self-existing, while in fact their "content" depends on their being perceived and understood by some brain. This creates the illusion that we are in the presence of three separate items: the neural (and motor) process resulting in the writing or drawing, the cultural artifact, and the knowledge or feeling encoded in the latter. The next step is to collect all such bits of knowledge detached from brains—i.e. all the problems and data, theories and plans "in themselves"—and endow such a collection with a life of its own. The final step is to give a name to such a collection of items allegedly hovering above brains and society—e.g. the "realm of ideas", the "objective spirit", or "world 3". (See, e.g. Plato, Hegel, Bolzano, or the later Popper.) In this way the illusion is created that such "worlds" of knowledge and feeling persist or subsist once they have been created by concrete individuals in specific social circumstances, and moreover that they can interact with living beings. Actually those collections do not constitute worlds (systems), for they are quite heterogeneous, particularly if cultural artifacts are counted among their inmates. Worse, there can be no empirical evidence for the hypothesis that such ideal "worlds" lead an existence separate from living brains. (Cf. Bunge, 1981a.)

To return to learning. The statement that somebody has learned a bit of knowledge is ambiguous. It may signify that she has created some new knowledge, or that she has grasped a bit of "existing" knowledge—existing, that is, as a process in someone else's brain or encoded in some cultural artifact such as a book or a film. The difference is that between production and consumption, and it is both a psychological and a social difference. It is psychological because producing new knowledge is generating psychons of a type that had not existed before in the evolution of the species, whereas to learn a bit of existing knowledge is to generate a psychon similar to one that had already been activated in someone else's brain. The difference is also social, for 'original knowledge' means "knowledge not available to anyone else before".

A bit of knowledge, whether original or unoriginal, may be thorough or partial, and it may be of high or low grade. Thus we may have partial or full knowledge of a gossip or of a theorem. So learning, whether afresh or second hand, comes in degrees. (Moreover we shall postulate that only constructs may be fully known. But this must await Section 5.) Unfortunately we still do not have a measure of degrees of knowledge.

As for quality, recall the (unclear) difference between knowledge and wisdom. The wise person is eager to learn discriminately. Knowing (having learned) much is not the same as being wise. A person may be a mine of information, yet quite incapable of creating new knowledge or correctly evaluating knowledge produced by others. Unlike erudition, wisdom is quality knowledge: it is knowing important things and knowing how to find out more of the same. Beware of those who claim that wisdom is disjoint from, and superior to, knowledge: they are likely to be superstition mongers. When we hear T. S. Eliot complaining "Where is the Wisdom we have lost in knowledge?", we should reply: "And where is the knowledge you parade as wisdom?"

Our view of knowledge differs radically from that of the ordinary language philosophers who hold that to know *X* is to know how to talk about *X*. Such knowledge would be "embodied" in certain speech rules rather than in bodies of data or in theories. Thus we are told that we may use the word 'quark' just in case there is a rule on how to use it. The stipulation has the advantage that it enables anyone with a command of ordinary language to pass for an expert on anything that can be talked about in the language.

Our view differs also from the empiricist doctrine according to which every learning process is gradual and proceeds by trial and error. We have made no such assumption, although we did assume that every learning process takes time. For all we know a number of higher vertebrates can learn certain "things" at the first go. Besides, all learning is driven by motivation and expectation. Also, not all trials are tests: errors are not easily eliminated even after ending up repeatedly in disaster. Just think of war and prejudice. The weight of prejudice is such, that learning new ideas often requires getting rid of false preconceptions (Bacon's *idola*). Thus one of the main obstacles to the learning of mechanics is the old superstition that a moving body eventually comes to rest for exhaustion of a driving force, fuel, or impetus (McCloskey *et al.*, 1980). Likewise the science student who wishes to learn some philosophy must begin by criticizing two views he learned in his science textbooks, namely that all concepts must be defined operationally, and that theories are data summaries.

Finally, our view is at variance with the conception of "knowledge as a matter of conversation and of social practice, rather than as an attempt to mirror nature" (Rorty, 1979, p. 171). To be sure, communication disseminates knowledge and social practice checks it: there is no cognition in a social vacuum. Still, cognition is a brain process not a social one, and we must have some information before we can trade it in conversation. Likewise there is no respiration in a physical vacuum, but this does not prove that respiration is an atmospheric or an ecological process. Besides, what would be the point of inquiry if it did not result in a representation of nature (and society)? The view of knowledge as a matter of conversation and social practice may fit the sophist but is a caricature of the investigator, be he a scientist, a technologist, or a humanist.

1.2. *Knowledge Evolution*

Our qualitative representation of knowledge in the preceding section allows us to speak of the *state of knowledge* attained by an animal at a given time, namely by identifying such state with the total knowledge acquired and retained by the animal up until that time. We denoted such knowledge by $K(b, t)$ (Section 1.1).

This representation allows one to compare any two cognitive states, be it of the same animal or of different animals at different times. Such comparison may yield, in principle, either of the following results. One of the animals knows *more* than the other (or the same animal at a different time), the two *share* some knowledge though not all, and the two do not share any knowledge. The first case might be that of the lower animals capable of learning something; the second, that of all primates; and the third pigeonhole seems to be empty. We assume then that *any two humans share some knowledge* and that *every one of them knows something that the other does not.* Without some common knowledge we could not communicate with one another; without some idiosyncratic knowledge there would be no point in communicating.

(The comparison of cognitive states can be synchronic or diachronic. In particular it allows us to estimate the gain or loss of knowledge in the course of time. Calling $K(b, 1)$ the cognitive state of animal b at time 1, and $K(b, 2)$ that at time 2, we may say that the *knowledge gain* between times 1 and 2 is $\gamma_b(1,2) = K(b, 1) - K(b, 2) = K(b, 1) \cap \overline{K(b, 2)}$. The gain is null, i.e. $\gamma_b(1,2) = \varnothing$, if the animal has learned nothing during that period. What holds for individuals holds, *mutatis mutandis*, for groups, upon introducing the definition of group knowledge as the sum total (union) of the knowledge of its members. In obvious symbols, $\gamma_G(1, 2) = K(G, 1) - K(G, 2)$, where $K(G, t) = \bigcup_{b \in G} K(b, t)$.)

The same formal tools allow us to compare (in principle) the knowledge states of different communities, or even of mankind at different times. If we do so we may find that there are always gains and losses. Thus we know many "things" that our ancestors ignored, but we also ignore much that made the existence of our forebears possible (and of others that made it unnecessarily harsh). In any case individual knowledge develops and human knowledge evolves: the former normally grows, the latter grows over certain periods but not over others. (Caution: knowledge can neither develop nor evolve, for it is not a concrete thing. Only individuals develop and communities evolve. However, the expressions 'development of knowledge' and 'evolution of knowledge' are permissible as long as they are understood to be elliptical.)

There are several views on the evolution of human knowledge. They can be grouped into two classes: those which hold, and those which deny, that the evolution of human knowledge follows definite patterns. Let us take a quick look at two well-known members of the former class. The best known of them is dialectics, according to which every construct carries within itself the seeds of its own negation, so eventually turns automatically into its opposite. This opposite would at the same time cancel and preserve the previous stage, and would eventually be subject to the same fate, i.e. negation. This second negation, far from being identical to the first construct (or thesis), would synthesize the first and the second: it would contain whatever was valuable in them, so it would occupy a higher rung in the ladder of progress. (Do not ask for more precision or for the mechanism whereby one item gets transmogrified into its opposite: dialecticians are neither clear nor thorough. The doctrine was proposed several millennia ago and has never gone beyond the verbal and metaphorical stage.)

The dialectical schema of the evolution of ideas is attractive at first blush: it is simple, it promises continuous progress, and it can be exemplified provided one is not too exacting concerning the notion of dialectical negation. However, the doctrine cannot be taken literally, for the only clear case of negation of an idea, namely logical negation, is not dialectical. In fact a proposition and its negation do not join to form a higher synthesis but only either a worthless contradiction or a harmless tautology. Also, it is an idealistic thesis, for it concerns the development of ideas in themselves (i.e. nonembodied ideas) rather than that of brains or communities. Thirdly, dialectics is confirmed by some examples but refuted by others. Think of the many futile controversies—theological, political and philosophical—that have occupied so many good brains for so many millennia without ever yielding any new, let along superior, knowledge. Or think of the way the great scientific theories have been created. What was the dialectical movement (of ideas) that ensued in Archimedes' statics, or in Newton's dynamics, or in Darwin's theory of evolution, or in Maxwell's electrodynamics, or in quantum mechanics? No dialectician has taken the trouble of telling us. In conclusion, there may be examples of dialectical process in the evolution of knowledge but there are also counter-examples, so there can be no general patterns or laws of cognitive dialectics. And, since there are no such laws, the principles of dialectics fail to explain or predict the evolution of knowledge. (More on dialectics in Bunge (1981a).)

The same holds for Popper's generalization of dialectics, i.e. what he calls the "method" of trial and error, summarized in the sequence: problem-theory-criticism (conceptual or empirical)—new better theory (Popper, 1972). For one thing this conception too is idealistic, for it deals with ideas in themselves in isolation from brains and societies. For another, not every theory, even if accepted, need be better than the theory it replaces: there are examples of retrogression or involution in the history of ideas. Thirdly, Popper's schema, which is a sketch of the usual conception of the scientific method, is normative not descriptive: it prescribes the way to go about investigating anything, but does not describe the actual cognitive evolution of mankind, or even of modern science. Hence it cannot be regarded as a generalization of the "laws" of dialectics. So much for two popular views on the evolution of knowledge.

It is doubtful that anybody has found *laws* of the evolution of knowledge. (See however Wilder (1981) for a set of alleged laws of the evolution of mathematics.) Consequently we do not even know whether there *are* any such laws. But we do know that, because ideas are not self-moving, we will not find any laws by examining ideas in themselves: we must investigate instead cognitive systems, i.e. learning individuals and communities, rather than the nonembodied "product" of their inquiry. This shift from ideas to their creators displaces the entire problem: it has now become a subproblem of the wider but more tractable problem of the laws of history. If there are such laws then the pattern of the evolution of knowledge is just an aspect of such laws. But, again, thus far we do not know whether there are laws of history. And in any case we must postpone this intriguing question to Vol. 6.

The result so far seems disappointing: we have succeeded only in proposing a qualitative representation of the state of knowledge and of cognitive change, and have expressed skepticism concerning the very existence of laws of such change. There are alternative approaches, two of which are quantitative. Let us see what they are and how they fare. The simplest of them is just to count knowledge items. This is not even a rough measure of knowledge, for the following reasons. One is that a mnemonist can memorize a huge amount of trivial information, whereas a foundational worker may be able to learn only a few but powerful items. Another, even worse difficulty, is the question of what is to count as a unit of knowledge: a proposition, a list of propositions (such as the one in a telephone directory), or a theory containing infinitely many propositions? In short, sheer numbers will not do.

A second and far more popular proposal is that of the subjectivist or Bayesian (or personalist) school of probability. It claims that (*a*) knowledge is a kind of belief, (*b*) belief comes in different strengths, (*c*) such strengths are measured by probabilities, and (*d*) probabilities are nothing else but degrees or strengths of beliefs, and so changes in probability values represent always changes in belief states. The centerpiece of the Bayesian school is the subjective interpretation of Bayes' theorem, which gives the probability of a hypothesis in the light of an item of empirical evidence, in terms of the prior (a priori) probability of the hypothesis together with that of the evidence and the likelihood of the latter given the hypothesis.

There are several objections to the theses that probabilities represent (only) states of knowledge or of ignorance, and the Bayes' theorem (or its information-theoretic rewrite) represents the learning process and even the evolution of human knowledge. Firstly, it leaves out problems and plans, methods and evaluations—in sum, whatever is neither hypothesis nor datum. Secondly, probabilities can be assigned to propositions only by decree: there are no objective criteria for such assignments since, according to the Bayesians, all probabilities are subjective or personal. Thirdly, a condition for the applicability of probability is chance or randomness—a condition absent from every fairly well organized body of knowledge. Finally, it is doubtful whether many people do learn from experience in any rational way, let alone in accordance with Bayes' theorem—particularly when probabilities are involved. In short, subjective probability does not solve the problem of measuring the state of knowledge nor, a fortiori, its evolution.

(Compare the claims of subjectivists with the actual way probabilities are used in science and technology. Here there are two possibilities: either one knows the probabilities of interest or one does not. If the former, it is either because of measurement or of computation, and in either case the posited probabilities are *objective* in the senses that they quantitate objective possibilities and that they are subject-free, i.e. public. If on the other hand the scientist or technologist is faced with total ignorance concerning the probabilities of alternative possibilities, or the distribution of a continuous stochastic variable, he adopts either of the following strategies. Either he abstains from assigning any values to the probabilities or the densities in question, or he makes hypothetical assignments, watches for the logical consequences—and makes the necessary corrections. He realizes that any such hypothetical assignments—e.g. equiprobability—are *hypothetical* and part of the particular model not of the mathematical theory of probability. On the other hand the Bayesian statistician makes arbitrary assignments of prior probabilities without regard to any matters of fact: he defies the scientific method. To the scientist or technologist any probabilities are probabilities of states or events, and therefore they (*a*) depend on the nature of the thing concerned and (*b*) must be either measured or conjectured regardless of the verdict of the subjectivist probabilist. More in Bunge (1981c).)

Finally, science and technology watchers and administrators have developed objective though ambiguous indicators of the volume and rate of growth of public knowledge. In fact there is an entire industry devoted to such measures as well as specialized periodicals, such as *Citation Index*, and annals such as *Science Indicators.* No doubt, such "scientometric" indicators do measure the *volume* of publications and their *diffusion.* Whether they also measure the volume and growth of *knowledge* is doubtful. Merely counting publications does not discriminate between original research and rehash, between deep insight and shallow information, or between revolutionary proposal and routine stuff. And counting the number of times a publication is cited indicates popularity rather than intrinsic value. The difference is important for, as a rule, the newer and deeper a contribution, the harder it is to understand and therefore the least popular it is bound to be at least for a while.

2. MODES OF KNOWLEDGE

2.1. *Basic Categories*

Classical epistemology dealt with the lone knowing subject and his knowledge, and did so in a static manner: it minimized the cognitive process and ignored its interaction with social behavior. The epistemology we are sketching deals instead with animals engaged in learning processes in their environment, and regards knowledge as a phase in those processes. Thus it interprets the conventional expression 'X is known' as "There is at least one animal of species S who has learned X under circumstances Y". At the same time we recognize the need for studying the "product" of the cognitive process regardless of the idiosyncrasies of the learning subject and her environment—i.e. the need for the study of knowledge.

Now, 'knowledge' is an omnibus word: it covers all learned skills (not the inherited ones though) and all manner of ideas. Indeed knowledge can be:

(i) *sensory-motor*—e.g. knowing how to walk (or limp) or how to type (however clumsily);

(ii) *perceptual*—e.g. tasting a lemon as bitter (or otherwise), or seeing a knoll of grass as green (or purple);

(iii) *conceptual* or *propositional*—e.g. knowing that the Earth revolves around the Sun (or conversely), or that the heart pumps the blood (or is the seat of the soul).

To put it into classical terms: knowledge can come from any of three "sources"—action, perception, or ideation. Therefore radical pragmatism ("Action is the only source of knowledge") does contain a grain of truth. So do empiricism ("Perception is the only source of knowledge") and rationalism ("Cogitation is the only source of knowledge"). By the same token each of these epistemologies is mistaken in excluding the other two "sources" of knowledge. (Caution: memory, traditionally regarded as a source of knowledge—about the past—can at most distort acquired knowledge, never generate it.)

The above distinction among the three knowledge categories should not blind us to the fact that they are interrelated. Thus conceptual knowledge can improve motor skills and perception: the trained hand (or eye or ear) performs better than the naive one. Besides, all three are simultaneously present in many cognitive activities, such as drawing and writing.

Note also that knowledge of any type may be correct or incorrect to some degree. Thus most of us would be unable to make anatomical drawings like those of Ramón y Cajal, or even Vesalius or Leonardo; most city dwellers fail to perceive (sense and identify) the sounds of nature as acutely and precisely as country folks; and all of us know as many falsities as truths. (And this trivially, in the sense that whoever knows the proposition p knows *eo ipso* not-p, as well as in the deeper sense that much of our conceptual knowledge is at best approximately true.) In short, knowledge is not necessarily correct. Nor does knowledge involve belief: I know many "things" (e.g. ideological doctrines) in which I do not believe, and I grant beforehand that some of my beliefs are false. Therefore the standard definition of "knowledge" as true belief is inadequate. More in Section 3.2.

A second useful distinction is that between *self-knowledge* (or knowledge of oneself) and *other-knowledge* (or knowledge of something other than oneself). Both can be obtained directly through perception, and self-knowledge also from feeling and emotion. (Feeling and emotion are not cognitive operations, but our awareness of them is a cognitive item.) They can also be known indirectly, namely by cogitation. And either mode supplements, checks, and corrects the other.

The ancient and wise injunction *Know thyself* can now be rendered more precise, to read *Know thy brain and thy social behavior.* To be sure one will never get to know much about oneself without the help of neuroscientists, psychologists, and social scientists. However, one can learn a lot about oneself by watching one's feelings and desires, modes of thought and behavior patterns—all of which *is* part of knowing one's brain and one's social behavior. A scientific study of all that will yield more detail and, in particular, a deeper understanding of why we feel, desire, think and behave the way we do.

Other-knowledge can be of things (natural, social, or artificial) or of constructs (concepts, propositions, theories, or proposals). And the latter may, though it need not, involve the former. Thus knowing a reasonably true atomic theory implies knowing something about atoms. On the other hand knowing some differential equations does not imply knowing any real things except the inscriptions representing such equations. (Rather on the contrary, we need some knowledge of differential equations in order to get to know something about atoms in any depth.)

We emphasize that knowing facts is not the same as knowing propositions about facts—a distinction that epistemic logic fails to draw. When perceiving fact f, or performing action f, we may gain *direct* knowledge of f; this knowledge is not necessarily propositional. Hence we are justified in asserting "I know f", rather than "I know that the proposition p describing fact f is true". On the other hand when learning about facts in books, or when working out scientific theories, we have *indirect* or propositional knowledge of them. These two modes of knowing, κ_1 and κ_2, compose as shown in the following self-explanatory diagram:

$$\begin{tikzcd}
\textit{Facts} \arrow[r, "\kappa_1"] \arrow[dr, "\kappa_1 \circ \kappa_2"'] & \textit{Propositions} \arrow[d, "\kappa_2"] \\
& \textit{Propositions}
\end{tikzcd}$$

Table 2.1 exhibits some types of knowledge distinguished by subject matter or referent.

A third useful distinction is that between first and second hand knowledge. *First hand* knowledge is acquired by personal experience, in particular research. *Second hand* knowledge is knowledge about first hand knowledge: it is communicated by word of mouth, the media, textbooks, or review articles. This partition of knowledge items does not involve any

TABLE 2.1
Types of knowledge with regard to subject matter or referent

Type	*Referent(s)*	*Field(s)*
Formal	Constructs	Logic, mathematics, semantics
Factual	Things, facts	Ordinary knowledge, arts, crafts, factual science, technology, ontology
Empirical	Experience	Ordinary knowledge, arts, crafts
Moral	Right conduct	Ethics, sociology, art
Epistemological	Knowledge	Epistemology

valuation. First hand knowledge may be worthless—e.g. I know there is a tiny inkspot on this sheet of paper—and second hand knowledge may be high grade—e.g. an insightful critical review of recent work on the effectiveness of psychotherapy. Knowledge of both types is necessary, for nobody can learn everything first hand. But we should not allow second hand knowledge to get the upper hand—as it did during the Middle Ages.

A related distinction is that between private and public knowledge. We may say that animal b has *private* (or privileged) knowledge of X if and only if there is nobody except b who has knowledge of X. Otherwise, i.e. if an item of knowledge is shared among at least some members of a society, it is *public* in that society. These are just definitions. Finding out whether a given bit of knowledge is public in some society calls for empirical investigation by psychologists, anthropologists, social psychologists, sociologists of knowledge, or historians of culture. Mere linguistic analysis will not suffice, notwithstanding those philosophers who claim that 'p is known' is an obvious example of public (or impersonal) knowledge (e.g. Williams, 1972). The fact that someone holds something to be known, without caring to mention who knows it, does not entail that such knowing can be impersonal or suprapersonal: it only indicates that the individual who makes that claim does not care to tell us who knows that particular item. The ordinary language expression 'p is known' must be analyzed into 'There is some animal that knows p'. Likewise when we say that 'x attracts (or repels)' we presuppose that there is something, other than x, that is attracted (or repelled) by x. *Moral*: Language is not a tool of analysis but an object of it.

There are two kinds of private and two kinds of public knowledge. Private knowledge can be knowledge of one's own states, in particular brain states, or secret knowledge, i.e. knowledge kept "classified". The former is direct in the sense that the subject has access to it without the help of anyone else. On the other hand getting hold of a secret concerning somebody or something requires data supplied by others—deliberately or unwittingly. However, knowledge of the two kinds can, in principle, be made accessible to others, i.e. rendered public in part. Surely your headache will not be felt by anyone else, but it may be guessed from your grimaces or from objective indicators such as, perhaps, the rate of endorphin synthesis in your brain. And, if physiological psychology continues to advance at its present pace, conceptual privacy may soon vanish. So much for the claim that all mental events are private.

Public knowledge too comes in two varieties: *ordinary* and *specialized.*

The former is shared by (nearly) all (adults) of a given community (at a given time), whereas specialized knowledge circulates (at a given time) only within very special learning communities, such as those of masons or mathematicians. The philosophers who possess no specialized knowledge tend to revere ordinary knowledge, claiming that it is sufficient for all purposes, or at least that it should be regarded as the Supreme Court of Cognitive Appeals, for being solidly anchored in experience and untainted by prejudice and theory. Both claims are wrong. The mere existence of mathematics, science, technology, and philosophy shows that common sense was found insufficient, for they start off where the latter stops or founders. Nor is ordinary knowledge as solid as it looks: it is mostly superficial, largely inaccurate, and remarkably incomplete. And in any event ordinary knowledge is shaped and updated not only by personal experience but also by the entire culture, as it feeds off the stale crumbs of science, technology and philosophy that may come within its reach. (By the way, there is no such thing as "common sense philosophy". This is a contradiction in terms: whatever is commonsensical is uneducated and therefore likely to be uncritical, shallow, and obsolete—in short, unphilosophical.)

The second variety of public knowledge, namely specialized knowledge, is supposed to be a result of specialized practice or of inquiry by individuals or teams possessing a special background and special skills. It comes in a variety of grades, from expertise (e.g. in cooking or managing or computing) to scientific, technological or humanistic knowledge. Here again, truth and usefulness are irrelevant: whereas some artisanal know-how is true and effective, some scientific (or technological or humanistic) knowledge is false and useless.

Plato's dichotomy between *doxa* (groundless opinion) and *episteme* (demonstrable science), though widely accepted, is inadequate. An electronic technician, though no scientist or technologist, uses well tested scientific and technological hypotheses, data and procedures, whereas a scientist cannot help hazarding speculations, and a technologist cannot avoid making recommendations on the basis of incomplete knowledge topped with intuition and judgement. The relevant distinction is not that between *episteme* and *doxa* but that between knowledge that is, or is not, a result of scientific (or technological or humanistic) research, as well as a possible subject of further investigation. In other words, the important distinction is that between research fields and belief systems. We shall return to this point in Section 4.1.

Another untenable dichotomy is that between *pure* and *practical* knowledge. Plato and Aristotle emphasized this distinction, praised the former and deprecated the latter. The pragmatists deny it, asserting that all "knowing is for the sake of doing" (Lewis, 1946, p. 3). However, some knowledge starts by being pure and remains so: it was acquired for its own sake and never finds application. Thus we do not "do" anything with cosmology, and nothing good has so far come out of the study of history—yet we cherish both and are proud of a culture that renders the cultivation of such disciplines possible and even desirable. However, it is hardly possible to forecast that a given piece of knowledge will remain pure forever. Electromagnetic fields, atoms, genes, fossils, brains, and many other things were initially studied with no practical purposes in mind, whereas nowadays entire technologies are concerned with using or manipulating them. In short, the pure-practical distinction does not amount to a dichotomy.

2.2. *Tacit and Explicit Knowledge*

Only some of our knowledge, whether sensory-motor, perceptual or conceptual, is conscious or explicit and expressible in some language: much of it is unconscious or tacit in the sense that we possess it without our knowing or without our being able to express it in any language. Thus craftsmen and artists, technologists and scientists, know how to do a number of "things" that they could not put into words. (The great Euler is reputed to have said that his pencil knew more than himself.) And any honest technology transfer deal stipulates that the customer will get not only artifacts and the corresponding operating and service manuals but also experts capable of teaching by example how to handle and service the system—precisely because not everything can be put into manuals.

A possible definition of the above concepts is this: If subject s knows p, then (a) s has *explicit* knowledge of p if and only if s also knows that s knows p or knows how to express p in some language; (b) otherwise s has *tacit* knowledge of p.

The difference has been explicitly drawn by a number of philosophers, in particular James (1890 I), and Russell (1918), who distinguished between *knowledge by acquaintance* (or *tacit* or *procedural* knowledge) and *knowledge by description* (or *explicit* or *propositional* knowledge). Polanyi (1958) emphasized the importance of tacit knowledge (which he called 'personal'); so did Oakeshott (1962). And both held that tacit knowledge is superior to explicit knowledge. This is a curious dogmatic statement to make for, by definition, tacit knowledge is ineffable and therefore hardly subject to examination, in particular evaluation.

Both tacit and explicit knowledge can stay private or become public, depending on the knowing subject, the degree of advancement of the field of knowledge, and society. However, it is obvious that explicit knowledge, for being expressible rather than ineffable, is far easier to share—provided there are no social barriers to information. (Remember that nearly every society regards knowledge of certain kinds as esoteric, or accessible only to a small group of initiates, be they priests, politicians, or intelligence agents.) But all this is rather obvious and therefore philosophically unproblematic.

A problem of interest to the cognitive sciences and epistemology is whether there are neurophysiological conditions that impose the dissociation between knowing how and knowing that or whether, with some effort, we could render explicit every bit of tacit knowledge. The scientific investigation of this question has only started. We have learned that amnesic patients can learn certain skills even if they cannot remember the information gained by using them. Thus patients unable to remember day-to-day events (i.e. who have lost short term memory) can be taught mirror reading without their remembering which words they had read (Cohen and Squire, 1980). This finding suggests that the dissociation between tacit and explicit knowledge is quite deep-seated.

We still do not know, then, whether there must always remain a residue of ineffable knowledge. But at least we seem to have learned that the right way to approach this problem is through scientific investigation rather than by resorting to a ready-made doctrine (such as intuitionism, rationalism, or empiricism). The problem is not one of mere academic interest: it is also of interest to educationists and to experts in the transfer of technology. Indeed, both groups would like to know whether every bit of knowledge can eventually be poured into a manual or a tape.

The tacit (or procedural)/explicit (or propositional) distinction could be used to discuss the problem whether computers can be said to know anything. It might be argued that they can acquire know-how but not know-that: that their knowledge is purely procedural—e.g. that they know how to add integers but not what addition or integers are. However, if we stick by our psychobiological approach we cannot admit that computers know anything because, having no nervous systems, they cannot experience plastic changes in them. All we can say is that computers are in some respects similar or analogous to knowing subjects, just as jets are in some respects similar to birds. These analogies are all-important for technology but of very little philosophical interest.

The tacit-explicit distinction intervenes also in current discussions in psycholinguistics. Empiricists claim that knowing a language is an instance of know-how in the same category as bicycling or hammering. Extreme rationalists, on the other hand, hold that knowing a language, like knowing anything else, is a case of know that (or propositional knowledge) in the same category as knowing that jets are fast or that the day has 24 hours. And Chomsky (1980) holds moreover that the basic grammar of a language is an inherited endowment somehow modified by experience and reason, perhaps in much the same way as songbirds improve by practice and imitation the songs they inherited genetically.

We will not repeat here what we held in Ch. 1, Section 3.1 about the inheritability of neurophysiological features that make it possible for a human to learn a language under suitable social circumstances. But we must pose the following problems. First, is it not likely that the young child's knowledge of language is a case of know-how in the same category as his knowing how to play with toys, and that such know-how turns into know-that only with formal education? Second, if knowing a language is to master the rules for generating grammatical sentences, and if such rules are innate or at any rate they are learned long before the speaker can form a notion of a rule, then are we really talking about *rules* proper, i.e. prescriptions for doing something, or rather about dispositions or even laws?

Whether the grammatical rules are inherited or learned as bits of know-how, they may be objective *patterns* ingrained in the brain rather than the constructs we learn at school. Thus knowing how to speak English amounts to having acquired the pattern of generating English sentences without necessarily *knowing* it, much as we learn to walk or play peekaboo. Likewise planets may be said to possess the laws of planetary movement without knowing them. Hence the expression 'knowledge of a language' is misleading if 'knowledge' is understood as being always conscious: it is mostly a matter of know-how rather than of know-that. Neither children nor illiterate adults nor the apes who have learned to manipulate human linguistic signals have explicit knowledge of language, hence they cannot make use of any grammatical rules in order to avoid or correct grammatical mistakes. They have only tacit knowledge of a language. Formal learning can bring this knowledge to the fore, i.e. transform tacit into explicit knowledge, patterns into rules proper.

Now two cautions against certain rather common confusions. The first is that tacit knowledge should not be equated with private or privileged knowledge (Section 2.1), for the former can often be shared or transmitted, if not verbally by example. And explicit knowledge may but need not be public: it may be kept secret. All public knowledge is or may be rendered explicit but the converse is false.

Our second caution is against mistaking public knowledge for objective knowledge, as explicitness and publicity are only necessary conditions for objectivity. Indeed we define objectivity as follows. First the general concept, applicable to both factual and formal knowledge. Let p be a piece of explicit knowledge. Then p is *objective* if and only if (*a*) p is public (intersubjective) in some society, and (*b*) p is testable (checkable) either conceptually or empirically. And now the strong or special concept of objectivity. Let p be a piece of objective knowledge. Then p is *factually objective* if and only if p has a factual reference (i.e. is about actual or possible facts).

Note again the difference between objectivity and intersubjectivity, a distinction that most epistemologists do not draw. (No subjectivist epistemology has any use for it.) Magical rules and religious dogmas may be intersubjective in a given society but they are not objective in the above methodological sense. As for the difference between objectivity *lato sensu* and *stricto sensu*, note that mathematical theorems are objective in the former sense but not in the second, whereas the statements made in science and technology are supposed to be objective in the narrow sense. (This point is of course being controverted in the social sciences, in particular in history. We shall take it up again in Vol. 6.) Finally, note that truth is not involved in objectivity. A statement may be objective and false, or true and non-objective. For example "$2 - 1 = 0$" is objective and false, and "I am not sure I'll ever finish reading this book" may be true but not objective. More on objectivity in Ch. 15, Section 2.2.

3. BELIEF

3.1. *Belief System*

In line with our biological approach to mind we construe beliefs, doubts and disbeliefs as brain processes of the mental kind. Like any other brain process of this kind, a belief has a genesis and it can change, even disappear, under the impact of other bodily (in particular mental) processes.

A possible characterization of belief and its cognates is as follows (modified from Bunge, 1980a, Postulate 7.3). Let b be an animal, u and v thoughts, and τ a time interval. Then:

(i) *b entertains* thought u during τ iff b has psychons that think up u, as well as other thoughts related to u, during τ;

(ii) *b believes* thought u during τ iff b entertains only u during τ (i.e. the psychons for other thoughts, related to u, are not activated during τ);

(iii) b is *doubtful* (or *undecided*) between thoughts u and v during τ iff b entertains both u and v alternately during τ, i.e. in such a way that the activation of the psychon for u inhibits that for v and conversely, i.e. cyclically.

Being brain processes, believing, doubting and disbelieving can in principle be investigated empirically (by neuropsychology). And, because the holding of certain beliefs controls social behavior, belief can also be investigated by social scientists. In fact it is being investigated by social psychologists and other workers. Such empirical approaches are of course at variance with the a priori approach adopted by the philosophers interested in the "logic" of belief (e.g. Hintikka, 1962).

Like any other brain processes, beliefs come in different strengths. We may grade them between -1 (maximal disbelief or rejection) and $+1$ (maximal belief or acceptance); and we may assign the value 0 to any thought that we are as strongly inclined to accept as to reject. More precisely, call B_b the collection of thoughts that animal b can initiate at time t, and T the set of all instants. We conjecture that there is some (presently unknown) function w_b from the cartesian product $B_b \times T$ into the unit real interval $[-1, 1]$, whose value $w_b(x, t)$, for x in B_b and t in T, is the *weight* or *strength* of x for b at time t.

Presumably, the values of w_b for different thoughts and times could be determined empirically. Such empirical research would show that belief strengths change in the course of time, occasionally in a dramatic fashion. If we can determine the collection B_b of thoughts of animal b, together with their respective weights, we have *eo ipso* determined the *belief system* of b, which we define as $\mathscr{B}_b = \langle B_b, w_b \rangle$.

To be sure, we have not determined the weight functions w_b but have merely expressed the hope that they may one day be determined empirically. As a matter of fact beliefs are already being subjected to experimental investigation, which is not surprising considering that they are brain processes rather than inmates of an immaterial mind. Being brain processes they can be influenced by suitable cognitive stimuli as well as by the subject's own ongoing brain activity. For example, a subject led to believe that she had been touched with the leaves of a harmful plant (e.g. poison ivy), while in fact she had been touched with a harmless plant, may develop flushing, itching, and erythema (Barber, 1978). The findings of social psychologists, on the way belief can be manipulated, are, if anything, even more dramatic: see the classical studies of Sherif (1936) and Asch (1952).

Another problem concerning belief that has been investigated experimentally is the discrepancy between what we believe and what we *say* we believe. For example, in a given English speaking community most of the women may pronounce 'student' while claiming that they always say 'stjudent', which is the socially accepted pronunciation; men behave in the dual manner. (It is not that all those subjects lie, except to themselves: they may not be aware of the discrepancy.) In any case of this kind it is the experimenter's task to fill out the following matrix:

	Professing to believe or do *p*	Not professing to believe or do *p*
Actually believing or doing *p*	*a*	*b*
Actually not believing or doing *p*	*c*	*d*

with $a+b=1$ and $c+d=1$. If all subjects are perfectly truthful (to the experimenter and to themselves), $b=c=0$. In actual fact this situation is seldom encountered. I.e. most of us do not quite know what we believe or do—which is one more argument against the definability of knowledge in terms of belief.

To return to the belief weights w_b. Since beliefs are brain processes, in principle they might be assigned objective probabilities conditional on experience and circumstances. One might speak of individual b holding belief u at time t, with probability p (or of the individual's propensity or disposition to believe u at t). In such case we would set $w_b(u, t) = 2P_{bt}(u) - 1$.

And, of course, one might then introduce the conditional probability of a given individual switching from one belief to another. But, as noted, such probabilities must be objective, for it makes little if any sense to ask an experimental subject to reply to questions of the form 'What subjective (or personal) probability do you attribute to that proposition (e.g. the Schrödinger equation): 0.7, 0.8, 0.9, or 1.0?'. And they must be conditional: a person accustomed to evaluating beliefs critically is less gullible than one who has received a dogmatic education, and so the probability of his acquiring a belief in the ghostly is smaller than the average.

The preceding considerations do not carry over, without further ado, to groups of animals, such as professional groups or social classes. To be sure ideologists and even some social scientists sometimes claim that the bourgeoisie, or the proletariat, or some other social group, holds this or that belief, or has this or that belief system. From a psychobiological viewpoint this claim is false, because social groups do not have collective brains. (On the other hand the claim does make sense in the context of objective idealism, where there is a body of ideas floating around, which some individuals can grasp albeit only imperfectly.) However, the notion of group belief, or belief system of a group, can be rendered rigorous and useful in the following way. Form the intersection of all the beliefs of the individual members of a group, and the family of their belief strengths: i.e. collect all the beliefs that the group members share (hold in common), and assign each its weight. The result is this: The *belief system of group G* is the structure $\mathscr{B}_G = \langle \bigcap_{b \in G} B_b, \{w_b \mid b \in G\} \rangle$.

The intersection of the beliefs of the members of a group of animals of the same species is never empty. But if it is small, as it happens with every wide group and every intensely divided society, the concept of group belief is not of much use, and the social scientist is forced to subdivide the given group into more homogeneous groups. But when the intersection is large, as is the case with homogeneous groups, we can speak of *prevailing opinion*, or *climate of ideas*, or "spirit of the times" (*Zeitgeist*)—provided we do not forget that such prevailing opinion is neither held by a single individual nor by a ghostly collective mind, but is a construction out of individual belief systems.

We should not underrate the weight of prevailing opinion on inquiry. Indeed such prevailing opinion may be favorable, unfavorable, or indifferent to a given line of inquiry (or research project). If favorable, "it" will encourage the project to the point of overlooking blemishes and discouraging competing projects. If unfavorable, "it" will exaggerate shortcomings and erect obstacles—which may either kill the project or force the investigators to be more ingenious, resourceful, careful, and critical. In either case, whether favorable or unfavorable, prevailing opinion is double-edged. (It works like a two loop control system, one of the elements providing negative, the other positive feedback.)

We are all sensitive, in some degree or other, to prevailing opinion and group pressure. Hence everyone is more or less suggestible and gullible, in addition to taking the good faith of others for granted. This makes us all more or less easy preys to opinion manipulation by teachers and preachers, politicians and ad-men. Contrary to widespread opinion, not even scientists are immune: the chemist who would not accept uncritically reports on success in synthesizing a certain molecule may fall in for homeopathy, psychoanalysis, or monetarism. A nationwide Gallup poll conducted in 1978 to assess the degree to which Americans believe in the paranormal and the ghostly gave the following results: 57% believe in UFOs, 54% in angels, 51% in telepathy, 39% in devils, 37% in precognition, 29% in astrology, 24% in clairvoyance, and 11% in ghosts. At about the same time it was found that belief in the paranormal is much higher among university students than among the public at large—a sad comment on the failure of the university to educate (Greenwell, 1980).

Why do so many people hold such groundless beliefs at a time when we are supposed to embrace science and technology? Presumably because some of those ideas seem to explain easily a great many phenomena, others are comforting, still others promise instant knowledge or power, and most of them have been received uncritically at an early age from the previous generation along with fairy tales and religious dogmas. In all such cases belief is supported not by argument or theory, let alone empirical evidence, but by tradition and a natural disposition to receive whatever one is given, as well as by the wish to secure cheap protection. (It is said that all risky and highly competitive professions are ridden with superstition. Sailors and airline pilots, truck drivers and stock brokers, soldiers and prostitutes often wear amulets.) The critical attitude and scientific inquiry are still recent and uncommon. Still, interestingly enough, few believers in those superstitions act consistently on the strength of such beliefs. For example, believers in astrology seldom choose their profession by consulting their horoscopes. There is always a gap between belief and action, principle and deed.

Experience is no deterrent to superstition because it can be interpreted in terms of the latter. On the contrary, we often acquire superstitious beliefs from having experienced certain coincidences and from our unwillingness to admit chance (a very modern idea that has not yet seeped down). This has been suggested by a classical experiment on the origin of superstition in pigeons. Instead of reinforcing "good" behavior, Skinner arranged for food to be delivered to them at regular intervals regardless of the animal's behavior. (I.e. he gave them adventitious reinforcement, which is what we do with our children when feeding them cookies and TV when they return from school regardless of their grades.) It turned out that one bird was conditioned to turn about the cage, another thrust its head into the upper corners of the cage, a third developed a tossing response, and two birds a pendulum motion of the head and the body. "The conditioning process is usually obvious. The bird happens to be executing some response as the hopper [food dispenser] appears; as a result it tends to repeat this response" (Skinner, 1948, p. 168). True, there is some evidence that such superstitious behavior does not occur in rats unless they have hippocampal lesions (Davenport, 1979). Still, chance coincidence must play some role in the formation of groundless beliefs even among higher vertebrates. And among humans docile reception of traditional belief is often socially rewarded.

Uncertainty is unpleasant to most of us, and this is why dogma is so popular. Indeed the adoption of dogma removes uncertainty, for a dogma, or at least a clever one, has ready-made answers to all possible problems of a kind. On the other hand inquiry, particularly in science, technology, and the humanities, creates new uncertainties for every uncertainty it removes, as every research problem ends up, in the case of success, by posing new problems while solving some. Thus, inquiry does not decrease uncertainty. But of course this is not the unsettling and paralyzing uncertainty produced by the failure of dogma: it is the stimulating uncertainty that promotes further inquiry. (If only for this reason the information-theoretic model of the growth of knowledge is inadequate, for it equates such growth with information gain, which would in turn be the same as decrease in uncertainty.)

Having condemned dogmatism let us now sound a warning against radical or systematic skepticism. If we were skeptics all the time we would abstain from making choices and decisions, as well as from acting on them. Consequently we would soon die—ignorant to boot. Radical skepticism, in particular skepticism about all our own perceptions and thoughts, has no survival value. Here as elsewhere a middle course is advisable, namely *methodical skepticism*.

3.2. *Belief and Knowledge*

We saw in the preceding section that we do not always know *that* we believe or *what* we believe. And sometimes we profess to believe "things" we really do not know anything about, such as life after death, perfect rationality, and spotless democracy. Some people go even further: thus mystics and psychoanalysts claim that their doctrines must be believed in order to be understood. (Remember Isaiah's *Credo ut intelligam*—I believe in order to understand—and the psychoanalytic requirement that every practitioner be subject to analysis.) A few have gone to the extreme *Credo quia absurdum* (I believe because it is absurd). In all these cases belief is recommended as prior to understanding and testing. Believers in the supernatural or the paranormal are faithful to this maxim: rather than believing science they prefer to believe what flies in the face of evidence and reason. Thus Kierkegaard, realizing that Christian dogma is absurd, stuck to it and declared existence itself to be absurd.

The uneducated believes what he knows and even what he does not: he is basically a dogmatist, only occasionally an inquirer. The educated knows what he believes and does not quite believe what he knows: he is basically a skeptic, though seldom a systematic or radical one. In short, belief is not a condition for knowledge. On the contrary, knowledge is a condition for rational or justified belief (or disbelief or suspension of belief). *Knowledge, then, is not a kind of belief.* Yet, Russell (1948) and many other epistemologists have defined knowledge as a special kind of belief, namely as *justified true belief*. (More explicitly: *s* knows that *p* if and only if *s* believes *p*, *p* is true, and *s* is completely justified in believing *p*. See Lehrer (1974) for a fuller statement of the belief analysis of knowledge.) This view is refuted by all the cases of people who profess to believe what they really do not know, and disbelieve a number of "things" they know. A more sophisticated counter-example is this: The disjunction of an arbitrary proposition with a tautology is true, so according to the belief theorists we should be justified in believing it. However, such a disjunction cannot pass for knowledge, particularly if the nontautological component is arbitrary or indeterminate. Besides, according to the definition of knowledge in terms of belief, most scientific statements would not qualify as bits of knowledge because they are at best partially true (see Ch. 12, Section 1.1). Nor would abstract theories, such as set theory and group theory, qualify, for they are neither true nor false. Being inapplicable to the most interesting bits of knowledge, the belief analysis of knowledge is itself unbelievable.

A rational person will make some effort to know a proposition before believing or disbelieving it: his beliefs are special cases of his knowledge not the other way round. Consequently instead of defining knowledge as justified belief, a rational person will define justified belief in terms of knowledge. He may accept the following definitions:

(i) *s believes* $p =_{df}$ s knows p & s gives assent to p;
(ii) *s is justified in believing* $p =_{df}$ s knows p, and p is approximately true or has a model;
(iii) *s is justified in doubting* $p =_{df}$ s knows p and s knows of no grounds to assign p a definite truth value or a model;
(iv) *s is justified in disbelieving* $p =_{df}$ s knows p and s knows that p has been refuted or has no models.

The problem of the relation between knowledge and belief can be approached either descriptively or normatively. The descriptive study of cognitive attitudes, such as belief and disbelief, certainty and doubt, is a legitimate field of inquiry if conducted scientifically, as part of psychology. It is illegitimate otherwise, i.e. if conducted without regard for empirical testing. A normative investigation of cognitive attitudes, i.e. one serving as a basis for a rational theory of decision and action, should be empirical as well: it should be possible to check whether the norms it proposes are efficient, i.e. conducive to successful action. Clearly, any such normative theory must presuppose some notion of knowledge and some notion of truth, for othewise it may consecrate groundless belief, i.e. dogmatism.

One may go farther and demand that such a normative theory of belief contain the axiom that credences, or degrees of belief, be numerically equal to the corresponding degrees of truth. (That factual propositions are true or false to some degree or other is known to all scientists and technologists. For the notion of partial truth see Ch. 12, Section 1.1, and Appendix 3.) More precisely, we postulate that, if p and q are distinct propositions, and the degree of truth of p given q (as a baseline) is v, then the rational credence of p given (assuming) q should equal v. (On the other hand if p and q are the same, i.e. p is its own ground, and thus groundless except possibly for its consequences, then p should be assigned no credence at all.) A consequence of this postulate is that the truest propositions are assigned the greatest rational credences. Another is that, if p is true, then not-p is incredible. A third is that all the consequences of a true proposition are maximally credible. Clearly, any theory containing such axiom is normative not descriptive: it is a theory of rational or grounded belief.

The standard theories of knowledge and belief, namely epistemic logic and doxastic logic, first proposed by Hintikka (1962) and now active subjects of research (cf. Lenzen, 1980), are of a totally different kind. In fact they are a priori (i.e. "logics") and they do not use the concept of partial factual truth, so they are hardly relevant to scientific, technological or humanistic knowledge. To begin with, the basic concepts of epistemic logic, namely those of belief, certainty, and knowledge, are taken from ordinary knowledge. Surely they are symbolized, but symbolization is no guarantee of truth or depth. For example, the principle "If s believes p, then possibly p" remains hazy as long as neither belief nor possibility are adequately elucidated. Hintikka (1969) does elucidate the notion of possibility in model-theoretic terms: the outcome is the so-called possible worlds analysis of knowledge. However, the possibilities concerned are conceptual not factual, whereas in the case of factual knowledge we are interested in real (nomological) possibility. (See Vol. 3, Ch. 4, Section 2.) Secondly, epistemic logic is not interested in the grounds for holding beliefs—such as empirical evidence and harmony with previously confirmed hypotheses—and so it makes no contact with factual truth. Consequently it tolerates arbitrariness and irrationality, and so it is not a tool for examining beliefs with a view to justifying or criticizing them. Thirdly, epistemic logic deals with isolated propositions and arbitrary sets of such, which is not the usual case in science, technology, or the humanities. In sum, epistemic logic is not an efficient tool for analyzing knowledge, and thus belongs neither in descriptive nor in normative epistemology. It is just a *jeu d'esprit.*

It does not follow that Popper is justified in holding that belief and the study of it are unimportant. On the contrary, we live and die by our instincts and beliefs. In particular all our inquiries, valuations and conscious actions are guided or misguided by beliefs. Thus, we believe in the value of scientific research to know the world. Only, knowledge is not a special kind of belief, and therefore epistemology is not included in the study of belief; moreover, the latter belongs in psychology.

4. INQUIRY

4.1. *Field of Knowledge*

Knowledge comes in degrees, and so does its dual, i.e. ignorance. Unlike knowledge, total ignorance cannot be assigned a brain activity of a definite type: it is the absence of such activity. On the other hand realizing, like Socrates, that one ignores something, is a bit of knowledge and therefore a brain activity. There are two ways of overcoming ignorance. One, cheap but illusory, is to embrace uncritically some belief; the other, onerous but effective, is to engage in inquiry in order to obtain some first hand or second hand knowledge.

Consider the main steps in a typical process of inquiry.

Step	*Events in inquirer's brain*
1	Considers problem p.
2	Inquires about theoretical or empirical setting of p.
3	Thinks up possible solution s to p.
4	Makes preliminary check of s
5	Concludes that s is inadequate.
6	Searches for alternative solutions to p.
7	Comes up with candidate t.
8	Makes preliminary check of t.
9	Concludes that t may be adequate.
10	Searches for counterexamples to t.
11	Having found none (or having explained them away) declares t to be a plausible solution to p.
12	Decides to investigate t methodically.
13	Formulates tactical plan for investigating t.
14	Writes up proposal for research grant.
15	In the process finds new data or reasons relevant to problem p.
16	New information suggests reformulating or even radically changing p.
17	Above change forces modification of original research plan.
18	Writes up final proposal.
19	Works on problem while proposal is being considered.
20	Takes cognizance of rejection of research project on the ground that problem is worthless or not original, or that proposed method or suggested solution is inadequate or too original.

Inquiry is a particular kind of cognitive process: it is *directed cognition*. In fact inquiry stars with some problem found in a given fund of knowledge, it employs definite means, and aims at finding some thing or idea that may solve the problem. Inquiry takes then at least five items: a group of inquirers, an incomplete fund of knowledge, a set of problems (gaps in that fund), a set of research tools (conceptual or material), and a set of goals (cognitive or practical). Successful inquiry builds up an epistemic field as it proceeds: logic or geometry, physics or biology, engineering or computer science, and so on. Since we shall make much of the concept of an epistemic field in this volume and the next, we may as well proceed to give a definition of the concept. (See Törnebohm (1979) for a different though congenial concept.)

The ten-tuple $\mathscr{E} = \langle C, S, D, G, F, B, P, K, A, M \rangle$ is an *epistemic field* (or *field of knowledge*) at a given time iff, at that time,

(i) C *is a system* composed of persons who have received a special training, hold strong information relations amongst them, and initiate or continue a tradition of belief or inquiry;

(ii) S *is a society* capable of supporting and encouraging, or at least tolerating, C;

(iii) the *domain* or *universe of discourse* D of $\mathscr{E}$ is the collection of objects of the inquiry, i.e. the reference class of the specific concepts of $\mathscr{E}$;

(iv) the *general outlook* or *philosophical background* G of $\mathscr{E}$ is composed of (*a*) an *ontology* or view on the nature of things, (*b*) an *epistemology* or view on the nature of knowledge, and (*c*) a *morality* concerning the proper ways of acquiring, diffusing and utilizing knowledge;

(v) the *formal background* F of $\mathscr{E}$ is a collection of logical or mathematical theories taken for granted in the course of the inquiry;

(vi) the *specific background* B of $\mathscr{E}$ is a collection of propositions and procedures, other than F, drawn from other epistemic fields;

(vii) the *problematics* P of $\mathscr{E}$ consists of problems concerning the nature, value or use of the members of D as well as problems regarding other components of $\mathscr{E}$;

(viii) the *fund of knowledge* K of $\mathscr{E}$ is a collection of propositions and procedures obtained by members of C at previous times;

(ix) the *aims* or *goals* A of $\mathscr{E}$ are of course the target (cognitive, practical or moral) of the specific activity of the C's;

(x) the *methodics* M of $\mathscr{E}$ consists of all the general and special methods utilizable in $\mathscr{E}$.

The first three components of this ten-tuple will be said to compose the *material framework* of the epistemic field in question. (Clearly this is a misnomer in the case of formal science, the humanities and theology, all of which deal primarily with conceptual objects not material ones. However, the expression has the virtue of reminding us that at least the first two components of every epistemic field *are* material systems.) The last seven components of the septuple shall be called the *conceptual framework* of the epistemic field under consideration. We shall return to this distinction in Ch. 14, Section 3 when dealing with paradigms and revolutions.

We distinguish two main types of epistemic field: *belief systems* and *fields of inquiry*. In a belief system the components 3rd to 10th hardly evolve or, if they change, they do so exclusively as a result of controversy or of external pressure: witness the ideologies. On the other hand in a field of inquiry every component from the 3rd to the 10th changes in the course of time, and does so mainly as a result of inquiry within the field or within contiguous fields. Besides, every field of belief is self-contained or nearly so: it is neither supported by, nor supports, other epistemic fields: witness pseudoscience. On the other hand every field of inquiry overlaps partially with some other epistemic fields. More on this in Ch. 14.

Belief systems do not always change spontaneously and gradually into research fields. On the other hand some fields of inquiry may gradually degenerate into fields of belief, and this in either of two ways. One is that the given epistemic field was finite to begin with: it had a finite number of problems, all of them soluble in a definitive way, and such that their solution did not pose any further problems. (We call *finite* any such field of inquiry even though we are at a loss to find clear instances.) The other way is by the gradual decay of inquisitiveness among the field workers, i.e. as dogma replaces conjecture and complacent belief takes the place of risky inquiry.

We do not know whether there are any finite and therefore exhaustible fields of belief: all of the known ones seem to be potentially infinite even when they attack finite problems such as censing populations or mapping chromosomes. Indeed, nontrivial knowledge of fact seems always to be spotty and more or less inaccurate—as well as obsolescent because of the extinction of things of some species and the emergence of things of new kinds. No sooner a body of data or of theory is pronounced perfect, than some gap or flaw is discovered in it—and somebody suggests ways of correcting or completing it. Therefore it may be assumed, though perhaps not proved, that, as long as there are workers left in a field of inquiry, the latter will continue to be cultivated—perhaps so intensively and effectively that it eventually turns into a different field. The antecedent of this conditional statement used to be taken for granted since the 17th century, but must now be questioned in view of the increasing virulence of antiscientific ideologies. More on this in Ch. 13, Section 4.

Strangely enough, though inquiry occupies an increasing number of people, and even though we are becoming increasingly familiar with it, there is hardly consensus on its very nature. To some, scientific, technological and humanistic research are arts like poetry or music, for they demand imagination, dedication, and enthusiasm. To others, they are crafts that can be learned and practised by almost anybody. To still others, research is an industry—the knowledge industry. Finally, to many, scientific research and technological development are an immoral racket bent on destroying life. Curiously enough, there is a grain of truth in every one of these opinions. In fact at their best science, technology and the humanities are arts demanding very special callings, talents, and a passionate commitment. At their next best they are nothing but sophisticated crafts, only trickier than the craft of versifying or that of mixing sounds, but still crafts rather than arts. (Still, one draws the difference between mere craftsmanship, however superb, and the inspiration that alone can deliver original art, science, technology, or the humanities.) And it is also true that some research deserves being called an *industry*, namely when it deals competently with pseudoproblems or miniproblems. Finally, it is also true that some scientists, technologists and humanists are crooks—but they are only a few and they are easily found out. In sum, we do not know much about inquiry, beyond that it is interesting and many-faceted, hence worthy of being inquired into.

4.2 *How is Knowledge Possible?*

Is knowledge possible? If so, to what extent and how? The first question may sound facetious but it is a serious epistemological question and one that was not easy to answer before modern science and technology were born, i.e. at a time when most knowledge was mere opinion. Not only skeptics like Sextus Empiricus, Francisco Sánchez, and Unger (1975), but also dogmatists such as Plato and Nietzsche, have denied that we can get to know anything about factual matters. (Mathematics has seldom been questioned.) Their favorite gambit was to exhibit gaps and errors in the bodies of received opinion.

The classical mode of refutation of such radical skepticism concerning the possibility of factual knowledge is still valid. We show knowledge to be possible by exhibiting items of actual knowledge, thus making use of Aristotle's modal principle "If p, then p is possible". (*Trivial examples*: I know the address of my home, the tastes of my children, Maxwell's equations, the empirical formula of water, and the specific function of the heart.) This disposes of radical or *systematic skepticism*. And a consideration of its historical role shows it to be ambivalent for, although it can destroy dogma, it also discourages inquiry.

Methodical skepticism, or *fallibilism*, is a different matter altogether. It is the thesis that, although we can get to know something, such knowledge may be imperfect (neither complete nor entirely true), and is therefore susceptible to criticism and improvement. Fallibilism is a component of *critical realism*, i.e. the epistemology according to which we can represent and understand reality, though not exactly as it is. (More on critical realism in Ch. 15, Section 2.)

Fallibilism is not enough: it must be supplemented with another sobering element, namely a dose of *agnosticism*, i.e. the thesis that there *are* unknowns and unknowables. *Examples*: If the speed of light is indeed the ultimate speed, then we shall never know what is happening at the same time in a distant place; if the big bang hypothesis is true, then we shall never know what went on in the universe before that hypothesized initial explosion occurred; if the brain does not contain detectors and decoders of extremely low energy electromagnetic waves, then we shall never be able to communicate telepathically even at a short distance; if there are no laws of history then we shall never be able to forecast with precision any major social events.

Note the conditional form of our wagers: *If A (is true), then we won't be able to know or do B.* Such conditionalization is a protection against dogmatism. We do not wish to repeat Comte's and Spencer's mistake of drawing long lists of *ignorabilia* that turned out to be subjects of inquiry and even entire scientific fields, such as atomic physics and astrophysics. Comte and Spencer were merely projecting their own philosophical prejudices into the future. Any list of *ignorabilia* that we may care to compile must be based on current knowledge not current ignorance. Thus because we *know* that certain biospecies and human cultures have become extinct, we shall never get to know them adequately. (However, living fossils or remarkably well preserved remains may turn up if we do not give up the search.) Likewise because we *know* that every experiment is subject to accidental errors, we shall never know whether a particular measurement outcome is error-free. (However, we also know that such errors can sometimes be reduced by operating at extremely low temperatures, so there is hope.) In sum, our knowledge is and will always remain incomplete and inaccurate—but there is no knowing beforehand and exactly *what* will remain unknown. We do not know any laws concerning the evolution of knowledge enabling us to make such predictions.

We come now to the third and last of the initial questions, namely 'How is knowledge possible?' This is a classical problem in epistemology and psychology, though one that skeptics (for obvious reasons) and others have refused to formulate. The classical answers to this question are:

(i) *naive realism*: the mind has direct access to things without the intermediary of either the senses or reason—e.g. intuitively or because the brain reflects the world;

(ii) *empiricism*: the mind receives impressions from the senses, so that it knows (only) phenomena (radical empiricism); the mind knows phenomena through perception, and it constructs abstract ideas (logical empiricism);

(iii) *idealism*: the mind grasps self-existing ideas (Plato) or essences (Husserl); there is a pre-established harmony between mind and world (Leibniz); the mind constructs the object, and certain ideas are prerequisites for any experience (Kant).

Although there is something to be said for each of these schools, none of them is fully satisfactory. Naive realism is too optimistic, it has no use for transempirical concepts and mathematical theories, it fails to explain creativity as well as error, and it proposes no cognitive mechanism. Empiricism underrates reason and is therefore impotent to explain abstract ideas such as those of logic, set theory, and abstract algebra. Idealism downgrades experience and does not account for error, let alone for the need to test our hypotheses. Besides, idealism and empiricism ignore the brain and the social context of cognition. Because they place mind out of both nature and society, empiricism and idealism can give no correct explanation of the generation of knowledge. Such reification of mind and its detachment from the world renders knowledge mysterious: in particular it makes science look "miraculously improbable" (Popper, 1972, p. 28). More on all these *isms* in Ch. 15, Section 2, where scientific realism will be defended.

Neuropsychology and the epistemology attached to it approach the problem in a radically different manner. We regard the organ of knowledge (the central nervous system) as a material system placed right in the middle of the natural and social world. As part of the world, the central nervous system can obtain some "inside knowledge" of it. The brain can represent other concrete items by being acted upon by them and generating neuronal configurations similar in some respects to the represented things. In short the brain can know matter because it is material itself. (The mythical immaterial mind, standing off the world, cannot interact with the latter, so it must be assumed to create the world all by itself.) Moreover, because cognition is a process in a concrete thing, it can study itself like any other concrete process. And, because cognition is a biosocial process, it develops and evolves along with other processes occurring in the higher social vertebrates. Thus we can get to know something about knowledge with the help of biology, psychology, social science, and philosophy: the task of epistemology becomes feasible. But at the same time epistemologists must work much harder than heretofore: a priori pronouncements, even if insightful, won't satisfy us any longer.

The conditions that render knowledge possible are exactly those that have resulted in the emergence of animals endowed with a central nervous system. They are extremely special and therefore exceptional material conditions. If the universe were a high density solid block, no knowledge would be possible, not only because life would be impossible, but also because everything would hang together so tightly that knowing a little bit would require knowing the whole. Likewise, if matter were distributed much more thinly, the bonds among things would be so weak that no cells would self-assemble; and, even if they could emerge, they would be nearly isolated from the rest and thus would have no chance to communicate. Also, too short a life span would leave no room for learning: all perception and behavior would be controlled genetically. Besides such physical and biological conditions for learning, think of the social ones: the smartest animals are gregarious. Solitary animals can hardly learn from others. As a Leibnizian would say, ours is the very best world to be known—which does not entail that it was designed so that it could be known.

Finally, how about computers: do they know, and if so, is there any limit to what they can get to know? Most artificial intelligence practitioners claim that computers do know and that in principle there is no limit to what they can know. On the other hand the critics point out a number of limitations—e.g. that a computer can never know any statements lying beyond formal systems (because a computer program is a formal system describable as a Turing machine). Presumably, future computers could overcome or circumvent any such limitations *if* indeed they were capable of knowing *anything*. But they do not know anything if one admits any psychobiological notion of knowledge. The only way out for the computer cultist is to offer a redefinition of knowledge applicable to computers as well as to animals, and one not hinging on the mythical separation between body (or hardware) and mind (or software). So far such redefinition is not forthcoming. So far computers are only cognitive auxiliaries, albeit marvellous ones. They do not initiate inquiry and they do not create any new concepts, let alone hypotheses, theories, methods, or value systems. To hold that computers do know is to indulge in metaphor—like saying that the emergence of every new "generation" of computers constitutes a quantum jump or a mutation.

5. Concluding remarks

Most of us go about inquiring in an empirical way, guided or misguided by intuition and tradition rather than by any explicit epistemological principles. Nonetheless we often manage to join the negative aspect of rationalism (namely its a priorism) with the negative one of empiricism (mainly the collecting of data for their own sake). Little wonder then that most of us harbor heaps of groundless beliefs and act accordingly, i.e. irrationally.

For example, we sometimes believe in the causal or even magical efficacy of the word even in the absence of interlocutors; we seldom reckon with chance coincidences and try to give causal explanations of them; we are prone to believe what we want to believe, and so we tend to disregard or reinterpret unfavorable evidence; we tend to fall for any comprehensive but simplistic and untested doctrine; and we have an excellent memory of our hits but a poor one of our misses. In short, we are often the victims of epistemic accidents.

It may well be impossible to avoid all the epistemic hazards. But with some formal education, some research experience and, above all, with some critical reflection upon our own successes and failures, we are bound to succeed in bringing down the frequency of epistemic accidents. And if we realize also that nearly every epistemology is but a blow-up of some partial truth, we may also avoid espousing it dogmatically, and may continue instead our search for, or updating of, an epistemology free from major blunders and capable of inspiring research instead of misguiding it.

CHAPTER 3

COMMUNICATION

Learning is private but inquiry is social, for it is done in some society or other. The social character of inquiry shows in our dependence upon tradition, in our need to share our questions and answers with others, and in our doing so through language and other, more primitive, modes of communication, such as gestures and calls.

Communication is an essential ingredient of social behavior in all gregarious animals. Through it we share cognitive attitudes and findings, and we influence cognitive processes in, as well as the behavior of, other animals. Through communication we are able to find out part of what goes on in the brains of our conspecifics and, what is more, we can modify such processes and therefore their behavioral outcomes. In this way every cognitive process is a component of some communication network or other—a network that nowadays embraces the whole of mankind. For this reason the lone knowing subject of traditional epistemology is as useless a fiction as the Robinson Crusoe of neoclassical economics.

Stressing the social character of inquiry and communication does not entail ignoring the fact that language is also a powerful thinking tool. As recognized long ago, thinking is to a large extent accompanied by talking to oneself. So, language discharges two functions: a cognitive and a social one. Chomsky (1975) and his followers have stressed the former, studying language exclusively as a mental faculty. On the other hand Wittgenstein (1953) and his followers are mainly interested in language as a mode of social behavior. Actually these points of view are mutually complementary rather than exclusive: speech is a tool of inquiry and learning as well as a mode of behavior and a social glue.

1. SUBJECT AND WORLD

1.1. *Subject–Object Relation*

The pivotal notion of traditional epistemology is the relation between knower (subject) and known (object)—and, in particular, the relation between inquirer and world. Therefore a task of epistemology has always been that of investigating the general problems involving such relation. To be sure, subjective idealism does not face this problem for it conflates subject with object, and so transforms the subject-object relation into a relation between the subject and himself. But in any non-subjectivistic epistemology the distinction between knowing subject and object known (or rather inquired into) is axiomatic. We call it the epistemological *duality postulate*—not to be mistaken for mind-body dualism. (For an examination of realism see Ch. 15, Section 2.2 and Lovejoy (1929).)

The epistemological duality postulate is essential to science, technology, and the humanities. Thus astronomy is the study of celestial objects not of the astronomer's inner life; sociology studies social systems, not the scientist's own "perception" of social facts; technology designs artifacts (physical, chemical, biological or social) instead of studying the daydreams of inventors; and the humanities study the lives and works of thinkers, artists, and men of action, not the scholar's own ideation or behavior. This does not entail that astronomers must ignore the way they perceive celestial objects, or that sociologists must push aside the way they conceive of social systems, and so on. Every specialist must study not only the referents of his field of knowledge but also the ways to study them properly, precisely in order to screen out the distortions ("artifacts") introduced by his viewpoints and techniques. Such self-knowledge, instead of the disregard for the knowing subject, will help attain or improve the objectivity that is supposed to characterize science, technology, and the humanities.

The distinction between subject and object need not, nay ought not to, imply their separation. I.e. the dual*ity* of inquirer and inquired need not imply a dual*ism* wherein the inquirer is divorced from his object of knowledge, and experience and theory are removed from nature and society, to constitute an independent realm. Such epistemological dualism, the partner of the metaphysical dualism of mind and body, is to be rejected if cognitive processes and their externalizations are to be understood as both organic and social processes, and therefore within the reach of scientific research.

A scientific approach to the subject-object relation is then at the same time epistemologically realist and ontologically naturalist (materialist). To be sure, historically not every realist epistemology has been associated with a materialist ontology. Thus Aquinas held consistently a realist epistemology and a hylomorphic and even supernaturalist philosophy of nature. Conversely, it is possible for a materialist not to hold a realist epistemology but to maintain, e.g. that all knowledge consists of conventions and rules designed to facilitate biological and social adaptation. What does force one to adopt at the same time some form of epistemological realism and some form of naturalism is science not logic.

In other words, the subject-object distinction is correct and necessary as long as it is not transformed into belief in an utter separateness of man from his environment, as preached by the monotheistic religions and by idealism. Distinctive we are, separate not. In particular, science and technology are not detached from society but are social activities; and they do not stand across nature but are aspects of man's interaction with his environment. To put it in traditional jargon, the realist epistemology required by scientific, technological and humanistic research should be joined to a materialist ontology asserting the essential oneness, interconnectedness, mutability and lawfulness of all things, inquiring and inquired. (Note that we have written 'things' not 'objects', for there are non-things, such as constructs, that are objects of knowledge. More on this below.)

Another way of putting all this is as follows. The concepts of subject and object may be regarded either as mutually independent (not interdefinable) or as definable. Idealists have tried to define the object in terms of the subject (or of God). In particular, subjective idealists have attempted to define a material thing in terms of the sensations or the perceptions (or in general the ideas) it produces in a subject. Recall Stuart Mill's definition of a thing as a permanent possibility of sensation, and similar definitions by Avenarius, Mach, and at one time Russell and Carnap. Neither of them seems to have realized that any such definition is circular for including the very term to be defined. (Consider: "To be a *thing* is the set of all ideas elicited in act or in potency by the *thing* on some subject".) On the other hand objective idealism can be logically consistent but at the price of postulating a Supreme Being that exudes things as he thinks them up. By so doing the philosopher turns theologian and alienates himself from science and technology.

What about abstract ideas, such as those of triangularity and goodness? Do they not refute materialism and epistemological realism? They do so if construed as self-existing—i.e. provided one postulates immaterialism instead of trying to refute materialism by honest toil. The materialist has no trouble disposing of that opinion. He starts by noting that there is no evidence for the self-existence postulate: that all we know is that some animals are capable of thinking abstract ideas. And he goes on to postulate that such thoughts are brain processes, as assumed by physiological psychology. So, when the subject thinks of triangularity he creates this idea (brain process) instead of apprehending it as in the case of perceiving a mountain. In other words, if the object is an idea then it is part of the subject. In this case strictly speaking—ontologically—there *is* no subject–object relation. In this case there is only a cognitive activity of the subject—in particular her feigning that the "objects" of her cogitations are self-existing.

This has important consequences. One is that not every object of knowledge is a material object existing independently of every possible knowing subject: some objects are parts (actual or potential) of some subjects. Another consequence is that, paradoxically, the knowledge of logic, mathematics or philosophy is, strictly speaking, a form of self-knowledge, because original logical, mathematical and philosophical objects are "produced" by the self instead of being self-existing. However, they have the appearance of objectivity and publicity because we have purposively stripped them of any idiosyncratic features. In other words, abstract ideas are formed by abstracting from personal characteristics and circumstances: they do not bear any birth marks and so are universal, i.e. thinkable in principle by anyone (Bunge, 1981a). In contrast, my knowledge of my present mood is only mine (unless I care to disclose it to somebody else) and, for being mine, it is not universal. Which brings us to the problem of the knowledge of mind.

There are multiple accesses to the brain processes of the mental kind, from physiological studies of brain activity and investigations of the behavioral manifestation of such activity, to external documents such as things fashioned or destroyed by the subject, to introspection or its verbal expression. The latter has been discredited by behaviorist psychology but it still is, and will always remain, an indispensable source of psychological knowledge, particularly when complemented and controlled by the other sources. Only, we must not say that 'the mind knows itself by introspection, i.e. by contemplating itself'. A linguistic behaviorist might say that this is bad grammar, because contemplation is an irreflexive relation: a can contemplate b only if a and b are different. We say that view is bad biology, for it reifies functions (activities). What can be said instead is that, in introspection, one part of the brain inquires into what another part of the same brain is doing, or what one subsystem of the brain did a moment ago: introspection, like self-consciousness, is just the self-monitoring of the brain. Moreover introspection, though necessary to understand the mind, is insufficient, for it tells us only *that* we are having such and such subjective experience, not *how*, let alone *why*, we are having it.

1.2. *Inter-Subject Relation*

Because he can communicate in some form or other, every human being can teach others and learn from others—sometimes long departed ones, thanks to cultural externalizations such as written documents, drawings and tapes. This does not mean that cognitive attitudes, processes and their outcomes can be transferred the way goods change hands: learning something from someone else consists in going through certain similar brain processes that are not transferable and that most of the time cannot occur unless previous learning processes have taken place.

Communication is a kind of social behavior and it occurs in communication systems, be they relatively simple ones like the mother-infant system, or complex ones like an international television network. Every communication system is composed of three main components: sender, channel, and receiver. The system is active every time the sender emits a message that gets transmitted (usually with some distortion) through the channel, and the receiver succeeds in decoding it. Any of these components or even all three can be nonliving, but there is no communication system unless at least the sender is controlled, directly or indirectly, by some animal. (The receiver can be a robot. The sender too can be one, but it will function on behalf of some living being.)

Of all communication systems the most effective ones are those where transmitters are also receivers, i.e. where there is a two-way communication channel. The traditional classroom, with its lecturer and his passive pupils, was a one-way communication system. The modern class, where feedback is encouraged, is a two-way communication system that facilitates error correction as well as learning on the part of the teacher. Actually every society is, among other things, a communication system, for communication is a part of social behavior and therefore a member of the social structure (collection of social relations.) It is not only that cognition is influenced by social relations: every communication act, from asking a question to answering (or refusing to answer) it, from exchanging gossip to trading data, from listening to the news to selling a newspaper, is a social transaction that contributes to either social cohesion or social disintegration, to the growth or the decline of knowledge.

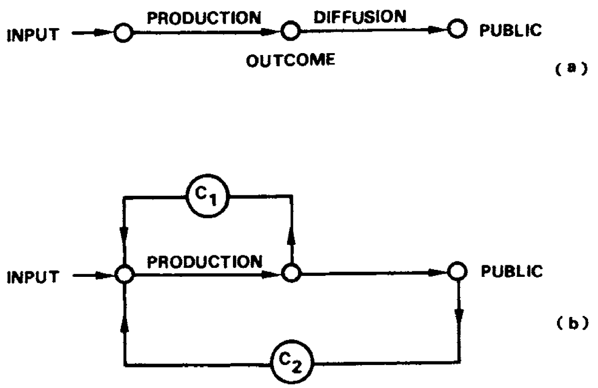


Fig. 3.1. Two views of the process of production and diffusion of knowledge. (*a*) Traditional views: open loop (no control). (*b*) Contemporary view: closed loops double control system: the subject corrects her own inputs (data, problems, etc.) in the light of her output, and society checks the whole.

From the point of view of systems theory, a communication system is a control system where the controls check the outcome of the process. Since there is the control by the knowing subject and by the society in which she is embedded, the system has two closed loops: see Figure 3.1. Without such control, irrelevance and error would go uncorrected, and society would neither encourage nor discourage any line of inquiry—for better or worse. Needless to say, the controls are in the hands (or rather brains) of all concerned, senders and receivers, producers and consumers of knowledge. This model contrasts with the open loop (no control) model of both empiricism and idealism: Table 3.1. The open loop model includes no mechanism, whether individual or social, for error correction, other than

TABLE 3.1
Three models of the production and diffusion of knowledge

	Empiricism	*Idealism*	*Realism*
Inputs	Data	Background knowledge	Background knowledge, data and problem
Transfer	Induction	Hypothesizing	Creative process
Output	Conclusions	New knowledge	New knowledge and problem
Control 1	——	——	Error correction
Control 2	——	——	Social checking

starting all over again, i.e. modifying the transfer function so as to obtain a different system. No such system change is necessary in the case of a closed loop control system.

We have avoided the term 'information' for several reasons. First, it is ambiguous, as it stands for both the act or process of conveying a message and for the content of the latter. Second, we communicate more than information or knowledge: we also transmit questions and commands, and we convey epistemic attitudes such as doubting, asserting, and denying. Third, since the inception of information theory (Shannon and Weaver, 1949), the term 'information' has acquired a technical signification that does not coincide with the ordinary language term, let alone with the traditional word 'knowledge'. Indeed information theory is concerned with the process of message transmission, not with what gets transmitted, which may be an equation or a nonsense string, a question or an order. The theory—like the communication systems it deals with, such as the mail and telephone services—is not concerned with the content of the messages the transmission of which it studies. Therefore information theory, though sometimes regarded as the basis of epistemology and semantics, is hardly relevant to them.

We shall have more to say on communication in Section 3 after having taken a look at the wider issue of the social matrix of the production and diffusion of knowledge.

2. SOCIAL MATRIX

2.1. *Cognitive Habitat and Niche*

Every animal has a habitat or region where it can live, as well as a niche in the ecological network. And every animal capable of learning has, within its total habitat, a *cognitive habitat* or region favorable to its cognitive activities. Thus at present the whole Earth and the Moon compose the human habitat, which may soon expand to encompass the entire solar system. But the Moon is not a good place to study anthropology, and Baffin island is not suitable for studying tropical zoology. Every human habitat is suitable, or unsuitable, to some degree or other, to learn about something.

In addition to a cognitive habitat, every animal capable of learning has a *cognitive niche* or set of possible cognitive states—or collection of "things" it can get to know. (A cognitive niche can be construed as a box in the corresponding cognitive space, or state space of the cognitive subsystem of the nervous system. Every cognitive niche is included in the total niche of the animal.) Animals belonging to different species can have very different cognitive niches, which sometimes hardly overlap. Think of man, mole, and louse.

The cognitive habitat of an animal capable of learning includes its parents and all the conspecifics with which it is in touch. In the case of social animals such contacts are not sporadic and random but permanent and regular. In this case every animal can learn from every other member of its community, and can teach some other animals no sooner it has learned something as well as how to communicate it. Learning is a social enterprise. We do not start from scratch but from the findings (and limitations and failures) of our teachers, and we learn from one another. Tradition and the flow of information are particularly strong among humans, and they are getting ever stronger, particularly with the establishment of communication links and the invention of cognitive records such as drawings and writings. However, this social aspect of learning should not be exaggerated: we learn *in* society but it is the individual, not society, that does the learning, for society is brainless.

The union of all the individual cognitive niches may be called the *public cognitive space*, or the total cognitive space of society (or mankind). One advantage of an (ideal) free society would be that each member of it would have access to any region of this public cognitive space, i.e. to the cognitive abilities and achievements of his fellow men. This possibility does not exist in societies divided into groups (e.g. priestly, professional or military castes, political parties or corporations) that exert a monopoly on cognitive activities of certain types. Where the public cognitive space is not partitioned into water-tight cells, an individual can learn much and quickly.

Man does not evolve certain cognitive abilities except in certain societies. For example, hypothetical reasoning, or the ability to reason in terms of *ifs*, is the principal novelty in the cognitive development of the child reaching adolescence in urban communities. This stage is seldom reached by people living in the countryside or in backward villages, let alone in preliterate societies. Here the subject is incapable of adopting a detached attitude and of contemplating situations or views other than his own, or of taking an interest in questions that go far beyond his immediate field of interest (Piaget, 1972; Luria, 1976). Schooling, even in the village, has dramatic effects, not only on cognitive attitudes but also on affective ones such as punctuality, discipline, health, nutrition, family size, and sensitivity to public issues—all of which have in turn a noticeable effect on economic growth (Lewis, 1955; Denison, 1962; Becker, 1964). In sum, human cognition is social through and through. Consequently psychology cannot study it properly unless it joins forces with sociology.

Take the social inhibitions, as well as the lack of social stimuli, to inquiries of certain types. A random sample must suffice. (*a*) The monopoly on literacy and inquiry, which was universal until recently, is a major obstacle to inquiry. (*b*) The extreme division of labor between manual and intellectual workers, and the low social status of the former, has been a major obstacle to scientific and technological innovation: craftsmen had no incentive to invent or to adopt new ways of increasing the quantity or the quality of the product, and intellectuals to engage in experimental inquiries. (In some nations, such as the U.S.A. and the U.K., scientists and technologists are not supposed to do their own machining.) (*c*) The prevailing value system may place little if any value on basic knowledge—this being why China, India and Islam did not contribute significantly to the building of modern science (Roche, 1976). (*d*) The prevailing ideology may discourage or even ban entire lines of research—e.g. of evolutionary biology in a theocratic state, and of social science in a totalitarian one. (*e*) A dogmatic school system will inhibit inquisitiveness and a critical attitude—whereas an excessively unstructured school will fail to teach intellectual discipline. (*f*) The preparation for, and waging of, war may accelerate the pace of destructive technology (drawing on a fund of basic knowledge). But it interrupts basic research by diverting human and economic resources—and by killing budding investigators in the battlefield. (*g*) The censorship exerted by organized dogmatism (church, party, clique, school) protects error from criticism and blocks the diffusion of new approaches and new results incompatible with dogma. Whatever does not fit with the latter remains unnoticed or, if noticed, is suitably "interpreted" (Fleck, 1935). (*h*) Intellectual fashion spurs research into the fad concerned but, by the same token, it diverts attention from other fields. (*i*) The current method of funding research encourages safe investigations expanding existing fields rather than opening up new ones. Indeed peer review tends to guarantee orthodoxy and suppress originality, encouraging researchers to swim in the main stream. (*j*) The requirement to remain within a given specialty makes for narrowness and blocks the diffusion of knowledge across cognitive fields. Trespassing should be rewarded not penalized, for it often gives rise to new approaches and occasionally even to new fields—as was the case with operations research, computer science, molecular biology, and physiological psychology. (*k*) Society is not always quick to adopt improved ideas, procedures, or things. It will accept a novelty only if it is quite obvious that it fills a vacuum. Even so the resistance of people who have vested interests in the old must be overcome or bypassed: remember that "One person's innovation is ordinarily another's destruction" (Brewer, 1980). See Figure 3.2.

A few centuries of relentless growth of knowledge has made us forget that this is not a law but a recent trend, and that the right to learn, like any other right, is not a birthright but must be conquered or defended. In some societies most of the people are prevented from learning certain skills—if not by force at least because learning demands some leisure. Only a few societies recognize the right to know and make it effectively possible for everyone to learn. In most societies the individual is denied the right to learn about the major decisions that may affect him or her, and a fortiori to participate in the taking and implementing of such decisions. Every society has economic, political and cultural mechanisms for controlling the production and flow of knowledge: no modern society can afford to leave cognition totally in the hands of private initiative. (More in Ch. 13, Section 4.)

Having recognized the need to study the social matrix of cognition—and therefore the legitimacy of the sociology of knowledge—we should sound a warning against epistemic *sociologism*. This is the view that every cognitive activity and every bit of knowledge should be studied and evaluated *only* in

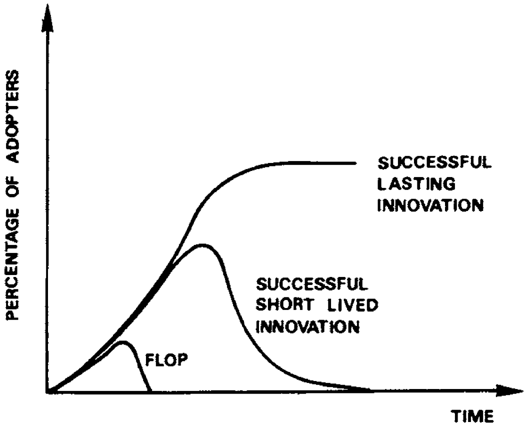

Fig. 3.2. The adoption of technological innovations.

the light of society and its history. Sociologism tells us that in the final analysis there is but one science: the science of man (Comte); that consciousness is determined (not just influenced) by socioeconomic conditions (Marx); that ideas are not so much in individual brains as in society—e.g. that Newton's physics was but a product of the first Industrial Revolution (Hessen, 1931); that the facts studied by science are not objective but are manufactured by the scientific community (Fleck, 1935); that truth is ultimately what the community of scientists decides to accept (Kuhn, 1962); that what distinguishes science from other cultural pursuits is its social condition (Ziman, 1979); and that an individual of genius is not one whose work is unique but, on the contrary, one "whose work in the end would be eventually rediscovered" (Merton, 1973)—so that a scientist of genius is "functionally equivalent" to a bunch of mediocre researchers. (By the way, Kuhn (1978) seems to have renounced sociologism to revert to internalism.)

Sociologism is wrong for the following reasons. First, all cognitive processes occur in some brain or other. Even a public utterance, or a formula written in a book, do not become cognitive items (i.e. processes in some plastic neural system) until somebody takes cognizance of it. Second, powerful new ideas and shattering discoveries are made only by exceptionally talented individuals: without these most of us would have no chance of participating, whether as beneficiaries or as victims, in any scientific or technological revolution. Third, although acceptance or rejection by a community are important to the fate of any new idea, popularity is not an indicator of truth anymore than impopularity an indicator of falsity: truth is a semantical and methodological category, not a sociological one. Fourth, although modern science and technology prosper only under exceptional social conditions, these come in a great variety, from capitalism to socialism, and from industrialization to semidevelopment. Moreover a mark of modern natural science is that its results hardly bear the seal of social circumstances, which on the other hand continue to exert deep influence on social science research. (For example, until the Great Depression economists were hardly concerned with unemployment, which since Keynes' *General Theory* (1936) has remained a crucial macroeconomic variable.) In short, society stimulates or inhibits inquiry in all fields, but does not do the inquiry because it has no brain. We do not have to choose between the isolated knowing subject of classical epistemology and psychology, and the all-powerful society imbued with a spirit of its own: we can choose to study the more modest but real inquiring subject-in-society. See Figure 3.3.

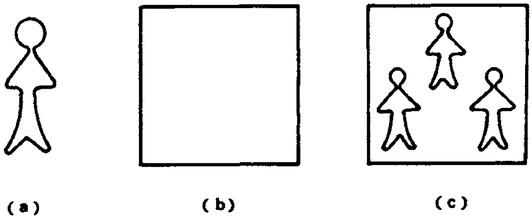

Fig. 3.3. Three views of cognition. (*a*) Traditional epistemology: the isolated knowing subject. (*b*) Sociologism: the brainless social framework. (*c*) Social neuropsychology: the community of learners embedded in a wider social matrix.

2.2. *Learning Community*

Every human being is a member of some *inquiring system* or *learning community*—i.e. a system of persons who learn by themselves as well as from one another by exploring and thinking, imitating and teaching, questioning and criticizing. And every learning community, whether advanced or primitive, has one or more *learning professionals*—medicine men or scribes, craftsmen or engineers, scientists or philosophers, teachers or journalists. Although these professionals may discharge other functions as well, their specific function is that of acquiring, utilizing or diffusing knowledge. These learning professionals form a subsystem of the cultural system that composes every community regardless of its level of development. Each of them holds information relations with other members of the community: some of them direct or interpersonal, others indirect, i.e. via couriers, correspondence, or publications. The potential clientele of these learning professionals is society at large.

In a modern society every learning community is divided into four main subsystems: the scientific, technological, humanistic, and artistic communities. Each learning professional is likely to be a member of several subsystems of the total learning community: e.g. a laboratory or some other unit, a university (or firm or government) department, a chapter or a professional society, an "invisible college" formed by knowledge consumers and evaluators, etc. In these conditions no learning professional is free from influences or completely devoid of cultural power over others. Typically, the crackpot is marginal: he is deprived of the benefits of stimulation and feedback. ("It is astonishing what foolish things one can temporarily believe if one thinks too long alone": Keynes, 1936, p. xxiii.)

The active member of a learning community shares in upkeeping certain inquiry traditions, updating them, and introducing new ones.

The organization of society as a whole, as well as that of each of its learning communities, is no less important for the conduct of inquiry than native intelligence, motivation, and industry. A mediocre intelligence can make substantial contributions to knowledge provided she is a component of a well organized learning community, whereas a genius is likely to go to waste in a cultural desert. The quick pace of innovation in science, technology, the humanities and the arts since the dawn of the modern era can be explained in terms of the emergence of a new type of society, more receptive to novelty and more mobile than the feudal society. The earlier explosion of knowledge that accompanied the birth of civilization about 5,000 years ago, and the no less dramatic explosion that accompanied the emergence of agriculture about 15,000 years ago, are further examples of the connection between modes of inquiry and social structure. Also, the revolution in technology and art that occurred about 30,000 years ago is likely to have accompanied a social reorganization which may have been prompted by a steep increase in population density, which in turn must have strenghtened and quickened the information flow.

Every specialized learning community, such as the community of biochemists or that of philosophers, is a social system. As such it can be represented by the triple *composition–environment–structure* (Vol. 4, Ch. 5). The *composition* of the community that cultivates a given field of science, technology, art, or the humanities, is of course the collection of all the workers in that field plus the support personnel (technicians, clerks, librarians, etc.) and their work tools. The *environment* of the community is the collection of all the items in the natural and social environment of it, including the subject matter in case this is material (e.g. the biosphere in the case of biologists, the whole universe in the case of cosmologists). And the *structure* of the community is the collection of relations of inquiry, teaching, receiving or conveying information, managing, etc., that give the learning community whatever cohesion and efficiency it may have. (We say that these activities are *relations* because this is what they are from a logical point of view. Thus inquiry is a ternary relation, for the standard form of a statement including the concept of inquiry is this: A inquires into B by means of C. Likewise teaching: A teaches B to do C.)

The study of learning communities is of course a task for social scientists, but their study as sociosystems has only begun. However, in order to understand any such community one must be able to understand what its members do: what problems they face, how they handle them, what kinds of hypotheses, data and methods they use, and so on. Unfortunately all too often the anthropologist or sociologist studying learning communities ignores this caveat and limits his study to observing the motions through which his subjects go—which is compatible with behaviorism but far off the mark of a scientific study of cognitive activities. Not surprisingly, the results of such studies are trivial or even grotesque. Ignorance is no substitute for inquiring about inquiry.

Every normal social system is propelled by cooperation as well as competition. The learning communities are no exception. Cooperation includes in this case help in transmitting skills and information, formulating or reformulating problems, devising hypotheses or methods, offering constructive advice or criticism and, in general, sharing knowledge. Competition includes making destructive criticism, proposing rival theories, methods or data, and fighting over the support of third parties, such as assistants, colleagues, and funding agencies. Cooperation gives individual workers the necessary support, and competition keeps them on their toes; competition helps find out error, and cooperation corrects it. Where cooperation falters, the system disintegrates; where competition disappears, the learning system may degenerate into a belief system.

In an increasing number of fields inquiry is conducted by *research teams* animated by an *esprit de corps* and where the division of labor, sometimes excessive, is compensated for by efficient organization. The research team, particularly conspicuous in natural science and technology since World War I—but still exceptional in the humanities—was a natural offspring of the scientific enterprise led by an autocratic leader. The research team is often democratic and can handle not only cross-disciplinary research but also unidisciplinary inquiry involving a number of skills unlikely to be mastered by a single individual—e.g. theorizing, computing, designing experiments, measuring, and performing statistical analyses. The publication summarizing the results of the inquiry is usually signed by the principal investigators, who acknowledge the help of their assistants, or by all the members of the team even if they number twenty or thirty individuals. Team research is far more common in experimental and applied science than in theoretical science. It is most successful when research can be planned in detail—which is possible only when known methods are employed to attain specific goals in a planned manner, which is not the case of the exploration of the unknown (Abelson, 1965).

The *research factory* is a different kind of inquiring system. It is usually set up by a captain of industry or a government official who controls resources, hires and fires, establishes the goals, and sketches the research or development project. Edison's Menlo Park, the Manhattan Project and the Apollo Mission are good examples of successful research factories. They were successful because their members agreed on a corpus of scientific or technological knowledge, on the proper methods to test new ideas and new artifacts, and on the ultimate goal. When such fundamental agreement is missing, mediocrity or paralysis is bound to set in. Although most research factories do not congregate large numbers of star researchers, they do ask for the advice of outside consultants capable of solving some of the toughest problems encountered by the team. Because research factories are mission-oriented, they discard any new problems and new ideas unlikely to be useful to attaining their goal. (Those who shun originality seldom get it.) Moreover the investigators employed by industry are not free to publish their findings, for the latter belong to their employers, who are anxious to patent and exploit discoveries, not to make them available to society. So, research factories curtail both the freedom of inquiry and the freedom of communication.

A third type of inquiring system is the *committee*. Committees may produce, analyze and evaluate research policies and projects, but of course they do not conduct original inquiries. Because most committees are watchdogs rather than explorers, they tend to be conservative. Galileo was condemned by a committee, and Einstein by political bureaus; likewise Marx and Darwin are still being condemned by churches and political groups. Since most people are afraid of novelty—either because they do not understand it or because they have vested interests in the old—the best result a committee can come up with when faced with radical novelty is an ineffectual proposal—such as referral to a subcommittee. Democracy has yet to solve the great problem of combining expert judgment with rule by committee. The key is agreement on both goals and means—a tacit agreement so much in evidence in the thinking and action that went into the selection of the horse and the camel. (It is false that a camel is a horse designed by a committee. What is true is that a committee of inexperts looks as though it were designed by a horse or a camel.)

The local, national, regional and international learning communities are the trustees of knowledge and they provide the mechanism for the steady production and diffusion of it. At the time of Galileo and Descartes the scientific community, then concentrated in half a dozen countries, counted about 200 scholars, mostly amateurs. (Armand Beaulieu, personal communication.) Today the scientific and technological community is spread over the entire world and is at least two million strong, not counting the support personnel. These huge numbers facilitate cooperation and intensify competition. The outcome is not only greater productivity but also higher and higher empirical standards. The ultimate test of a scientific, technological, humanistic or artistic innovation is its achieving international recognition.

The existence of learning communities explains simultaneous discovery and invention, which are otherwise mysterious. Popular explanations for such events are that certain ideas are "in the air" (objective idealism), or that they are necessitated by society, particularly the economy (vulgar materialism). The truth is that coinventors or codiscoverers share (*a*) certain brain properties, (*b*) certain work habits and values, (*c*) a tradition, and (*d*) a set of problems. If half a dozen talented people share a body of knowledge and values, and tackle a given problem at about the same time, it is not unlikely that a couple of them will come up with the same solution at about the same time. Cultural parallelism is no more mysterious than genetic parallelism.

We wind up this section with a couple of remarks. The first concerns group learning: it is sometimes held that not only individuals but also human groups can learn (Botkin *et al.*, 1979.) Literally taken this is impossible, for groups do not have a brain of their own. What is true is that (*a*) individuals in a group can learn from one another, and they can learn to think, feel and act so as to optimize the efficiency and the cohesion of the group, as a result of which (*b*) the group evolves.

Our second remark concerns the ontological status of inquiring systems. At first sight they are not concrete or material entities because they lack most of the properties characterizing physical or chemical systems, and because they make use of constructs. However, (*a*) any system composed of material entities, such as human beings, can be said to be material itself, and (*b*) inquiring systems are not composed of persons and constructs on a par but only of persons endowed with brains capable of conceiving constructs. The material/conceptual dichotomy is methodological, not ontological: it is only a convenient fiction to abstract ideas from the brains capable of thinking them up. (Cf. Bunge, 1981a.)

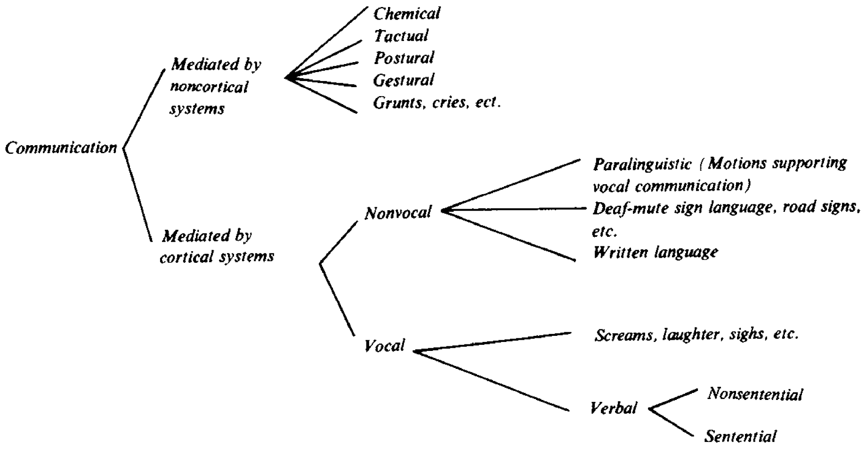
3. Communication

3.1. *Communication System*

All animals endowed with a central nervous system, from ant to primate, seem to be able to communicate, i.e. to send and receive signals carrying some information. (Cf. Sebeok, 1977.) Communication is particularly developed in social animals, where it discharges at least the following functions (Lindauer, 1971): (*a*) to inform other animals that they belong to the same species or even the same society; (*b*) to inform others what their position in the social organization is; (*c*) to inform others in what state the individual is (e.g. whether it is ready to court, fight, or communicate where food can be found); and (*d*) to give or receive instructions concerning tasks of social utility (e.g. to bring in food or take out refuse). Communication, then, is a powerful tool of biological adaptation and social organization. However, here we are mainly interested in communication as a means to acquire, elaborate, and share knowledge.

The key concepts involved in any comprehensive discussion of communication are those of signal, message, significance, understanding, and communication. Definitions of these concepts in psychobiological terms are proposed elsewhere. (*Treatise*, Vol. 4, Ch. 4, Def. 4.55, and Bunge, 1980a, Ch. 9, Def. 9.8.) Here we shall concentrate on communication systems and, in particular, languages. A *communication system* is a concrete (material) system composed of animals of the same or different species, as well as nonliving things, in some environment (from beehive to the universe), and the structure of which includes signals of one or more kinds. Signals are processes executed or controlled by some animals and capable of carrying messages to other animals able to decipher them. These signals must be physical or chemical processes: the mythical psychical waves do not work because they do not exist. And the communicating animals must be endowed with suitable sensors: there is no extrasensory communication.

There are a great many kinds of signal employed in animal communication:



Communication
Mediated by noncortical systems
Chemical
Tactual
Postural
Gestural
Grunts, cries, ect.
Mediated by cortical systems
Nonvocal
Paralinguistic (Motions supporting vocal communication)
Deaf-mute sign language, road signs, etc.
Written language
Vocal
Screams, laughter, sighs, etc.
Verbal
Nonsentential
Sentential

We are more interested in signals systems than in occasional stray signals such as grimaces, screams, or grunts. A *system of signals*, or *communication method*, is a (natural or artificial) collection of interrelated signals, involved in some communication systems, and allowing an animal to compose and convey messages addressed to other animals (primarily but not exclusively conspecific). A system of signals can be either inherited or learned, it may or may not contain a set of basic signals (e.g. words), and it may or may not be composed of an indefinite number of signals. Human speech and the American Sign Language, drawing and sculpting, pictographic and phonetic writing, musical notation and chemical notational conventions, mathematical and computer languages, are artificial systems unique in the animal kingdom.

Take for example the American Sign Language (ASL). Its expressive power is said to be as great as that of ordinary spoken language, though its rate of production is half the rate of the latter (Bellugi and Klima, 1979). Another example of a language is chemical nomenclature. The symbols for the 100 or so chemical elements, together with a set of numerals, suffice to form (by concatenation) the stoichiometric formula of any chemical compound. But in this case the syntax is neither conventional nor a product of a haphazard historical development: it summarizes chemical laws.

A *language* is a system of signals that are invented or learned rather than inherited. Moreover every signal in a language is either a simple signal or a complex one formed by concatenating two or more simple signals according to definite (syntactical) rules. There is no limit to the number of signals (hence messages) that can be formed in a language out of simple signals (e.g. words). (Mathematically speaking, a language is embedded in a free semigroup on a set of basic signals. Caution 1: The standard description of a language as a free semigroup is incorrect because in actual fact we can form only finite collections of strings of symbols of finite length. Caution 2: Some English words do not combine associatively. Thus '(small car) buyer' is not the same as 'small (car buyer)'.)

Many systems of signals, such as road signs, the human "body language", and the signals used by social bees, are not languages proper. Neither of them has a syntax, and the last two are inherited or instinctive rather than learned. Nevertheless some students of animal communication regard the systems of signals used by bees and ants as sets of conventions. Thus they state that taking the sun as a reference point, and "reading" the number of waggles or sound bursts as measuring the distance to the food source, are so many conventions. (See, e.g. Brines and Gould

1979.) But surely this is a misuse of the term 'convention', for it is admitted that such "rules" are wired in the insect's brain.

Human languages, on the other hand, are multiple, conventional, learned, and changeable. They are conventional because there is no law of nature commanding to name things in any one way, or placing noun and adjective in one order rather than another, and so on. (Caution: Although natural languages are conventional they are not the product of deliberate agreements but of cultural evolution.) Consequently any given linguistic convention can be replaced with another or even dropped altogether. And new conventions can be introduced provided they satisfy certain conditions ensuring over-all consistency as well as respecting what the French call *le génie de la langue*—whatever this may turn out to be.

So far as we know only humans have invented conventions and, in particular, linguistic conventions. However, there are indications that anthropoid apes can learn some of our linguistic conventions. A number of workers (Gardner and Gardner, 1969; Premack, 1971; Savage-Rumbaugh *et al.*, 1978; Patterson, 1978) contend that chimpanzees such as Sarah, Lana and Washoe, and gorillas such as Koko, have learned certain human languages such as ASL. They would master them to the point of communicating with their trainers as well as with some conspecifics, and to convey new thoughts not taught them, as well as to talk to themselves. The critics claim that these animals just respond to their teacher's previous utterances, that they have learned to use certain signals by sheer conditioning, and that the system of signals they use is devoid of syntax (Terrace *et al.*, 1979). The whole thing, according to them, would be a delusion, like the Clever Hans phenomenon, resulting from careless methods and anthropomorphic interpretation (Umiker-Sebeok and Sebeok, 1981).

The linguists who have become involved in the controversy—and there are not many—tend to disbelieve the thesis that beings other than man can make use of language. In particular, the transformational linguists pose the problem as follows. The fountain of a language is its grammar, which is composed of syntactical, semantical, and phonological rules for the production and understanding of correct sentences of the language. If an animal is capable of forming new correct sentences—new, that is, to the animal, and which is has not learned by rote—then it can be said to have mastered (to some degree) the grammar and thus the language in question. If on the other hand the animal does not form consistently any new and correct sentences, this is a clear indication that it does not possess a set of rules (a grammar) to generate the sentences of the language. Now, the empirical evidence for "ape language" is weak: it refers to a handful of apes and there is no hard evidence that they do produce sentences really new to them, rather than repeating sentences formed by their trainers. Some workers hold a stronger view, namely that (*a*) there is no favorable evidence whatever, and (*b*) there *can* never be any such evidence, for language is built into the human mind—perhaps to the point of not being learnable at all. Needless to say, there is no evidence for these countertheses either.

It would seem that the investigation into "ape language" should start all over again and be conducted in a more rigorous and thorough manner. In particular the following points should be taken into account. First, a more adequate definition of a language (in particular a human language) should be proposed. (I do not mean a more exact definition, for the one offered by the mathematical linguists, namely in terms of the concept of a free semigroup, is exact. What I mean is a definition fitting any ordinary language.) Second, not only apes but also other animals, in particular "talking birds" and songbirds, should be investigated. Third, the performance of apes and other animals should be compared to that of children for, after all, we hardly know how a child acquires language (Bindra, 1981). It may well turn out that a child's speech, too, is cued by his interlocutor, who may in turn be a victim of the Clever Hans phenomenon. Fourth, the following hypothesis is worth being investigated. When an animal learns to name things or events, it may proceed as follows. In a first stage the object and the symbol (word, chip, figure, etc.) elicit each a process in some neural system. Learning to name the object by the symbol consists in connecting the two psychons or in establishing a third psychon for both. And this is noting but conditioning, that *bête noire* of mentalism: Figure 3.4. As for new sentences, they may result from the sequential activation of psychons for learned words, or from the spontaneous activity of psychons of new types. Since apes and other animals have given ample evidence of inventiveness in other fields, it should come as no surprise that they can learn sentences and even form new ones. But this hypothesis has yet to be confirmed by carefully controlled experiment.

Why has the problem of "ape language" stirred such spirited controversy? There are several reasons for this. One is that the problem is tough, the evidence inconclusive, and our knowledge of the way humans learn to speak is not far superior to our knowledge of the way Sarah, Washoe, Lana, Koko and a few other cousins have learned to communicate using man-made signals. Another reason is the novelty of the

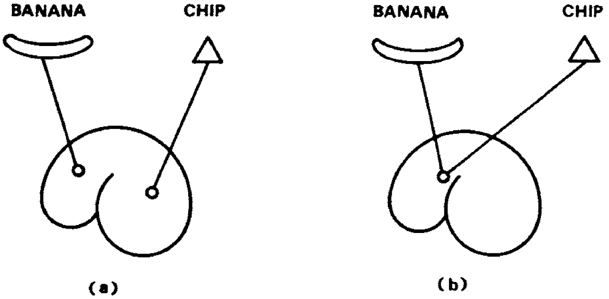


Fig. 3.4. Learning to name an object. In a first stage object and symbol activate different psychons. In a second stage a single psychon is activated.

thesis that animals other than men can talk, particularly in view of the traditional definition of man as "the talking animal". If true, the thesis would have profound implications for psychology (particularly psycholinguistics), anthropology (particularly palaeoanthropology and prehistory), and evolutionary biology (in particular that of primates). A third reason is that the thesis has ideological overtones. Indeed if the thesis is false, then it becomes easier to defend the view that the human mind has nothing to do with subhuman brains: there would be an unsurpassable chasm between man and beast, which evolutionary biology could not hope to explain. Thus the refutation of the hypothesis of "ape language" (or rather that apes can be taught some human languages and the mode of thought that goes with them) would bring comfort to the various religions and spiritualistic philosophies that hold .the dogma of the spiritual (and possibly partly supernatural) nature of man. Actually if the "ape language" theses were refuted the materialist need not concede defeat: he could still hold that language and thought are brain functions that have evolved biologically and socially from humbler neurophysiological functions.

Unfortunately we know next to nothing about the origin of language and, because any prehistoric and palaeoanthropological data we may get hold of will at best serve as circumstantial evidence, we may never be able to formulate anything beyond clever conjectures. (Cf. Lieberman, 1975; Harnad *et al.*, 1976.) However, since language is *inter alia* a means of communication, it is reasonable to conjecture that every major leap in the evolution that led from our remote ancestors, a few million years ago, to *Homo sapiens sapiens*, was accompanied by a major advance in communication. It seems also reasonable to hypothesize that the language of primitive man was quite different from ours: for one thing it may have been just a collection of words, and thus as agrammatical as baby talk. There is no reason to believe that it satisfied the definition of a language fashioned to fit modern languages. Unfortunately most linguists seem reluctant to accept any alternative definition, and thus they close the door to the very investigation of the evolution of language.

To return to the problem of language acquisition. Thanks to the work of developmental psychologists—Piaget in the first place—and neurolinguists, we are learning a bit about the development and loss of linguistic abilities. For example, it seems that language and substantive knowledge are functions of different brain systems. This is suggested by familiar experiences such as forgetting what a name stands for, and what the name of a known concept is. It is also suggested by the observation that a (semantic) aphasic knows that a cup is to drink from even if he is unable to name it. Moreover the surgeon can cut some of the neural links between speech and thought, as shown by commissurotomy patients, who are unable to say some of what they think. (A right-handed person who has had his corpus callosum cut cannot react verbally to verbal stimuli projected to his right hemisphere, but he may produce nonverbal responses indicating that he has understood the message conveyed by the stimulus.)

Furthermore it is possible that syntax and semantics are in charge of different psychons, as suggested by the finding that some neurological (and philosophical and sociological) patients produce gibberish sentences that are grammatically well formed. Also, reading and writing would seem to be controlled by different brain centers. Indeed severe dyslexia patients can write sentences which they are unable to read. Neurophysiological examination points to lesions in the angular gyrus (and usually also in the splenium) as causing dyslexia without dysgraphia. And lesions in the supramarginal gyrus have been shown to cause dyslexia with dysgraphia.

Further confirmation of the hypothesis that language and knowledge are functions of different brain systems is provided by the well known fact that illiterates and deaf-mutes can learn to play chess, paint, draw blueprints, and read maps, neither of which involves verbalized thinking. (Chess thinking is imagining moves, and paint thinking is imagining shapes and colors.) The very existence of nonverbal or nonsymbolic thought refutes the view, rather popular among philosophers from Plato to Quine, that all thought is symbolic or verbal, so that (methodological consequence) the study of language exhausts that of thought. Once more, empirical research has killed philosophical speculation.

Thought and language are then different. But they are coupled: learning to speak goes hand in hand with learning to perceive and to think, and each aids the other. Besides, using a language is a cognitive ability, so that knowing a language is a kind of knowledge, though not one of subject matter. Also, the more substantive knowledge we want to carry, the more linguistic container we need. In general all cognitive abilities—and language is one of them—are linked, and linguistic dexterity helps acquire and perfect other cognitive skills. For example, bilingual children all over the world do better at problem solving and "divergent thinking" (inventiveness) that unilingual ones (Lambert, 1981).

Our knowledge about language acquisition (and unlearning) is insufficient to give definite answers to certain questions that have given rise to a great deal of controversy in recent times. (The temperature of a debate is an ambiguous indicator: it may indicate profound ignorance of the subject, ideological implications, or both.) One such question is whether there is a special "capacity" for learning language—assuming we know what a "capacity" is. Whereas empiricists claim that language is learned like anything else, innatists hold that humans are born with a special capacity for learning languages—and some of them go as far as claiming that we are born knowing the main features of language. These conflicting theses are difficult to evaluate because of their imprecision: what does "general (or special) learning capacity" mean? The problem becomes clear when reformulated in neuropsychological terms, e.g. as "Are there any special neural systems ("areas", "structures") that do the language learning and no other?" The first conjunct of this problem has a definite answer in the affirmative: the Wernicke and Broca "areas" are the ones in charge of verbal language. (However, their location varies considerably with the individual.) But the second conjunct, namely the question whether such "areas" cannot learn anything extralinguistic, is yet to be answered or perhaps even asked.

A second controversy is closely related to the foregoing and it concerns the way we learn languages (cf. Sampson, 1978; Stich, 1979; Chomsky, 1980). Is it a step by step process, essentially one of trial and error operating on a blank slate (*tabula rasa*), as empiricism maintains? Or are we born with tacit knowledge of a Universal Grammar—common to all natural languages—as the innatists (or rationalists) hold? The latter have attacked linguistic empiricism holding that it does not explain why children learn so quickly the correct grammar: if they were to learn by trial and error they would never learn to speak at all, for it would take them an eternity to discover all the rules of the language from any given set of linguistic data. True, but the falsity of empiricism does not prove rationalism—the more so since there is not the slightest evidence for the inheritability of anything beyond the mere capacity or potential to learn languages (or farming or astronomy). What we do know instead is that all normal humans share certain neurophysiological characteristics and are born into some culture or other; and that both the *neural universals* and the *cultural universals* determine the ways we learn. Some of these, which are properties or regularities of concrete systems (neural and social respectively), could be the linguistic universals that Chomsky and his followers attribute to an abstract (and yet to be discovered) Universal Grammar.

To conclude this section, I submit that the problem of language learning is a scientific not a philosophical one, and therefore neither of the two philosophies involved, namely empiricism and rationalism, is competent to solve it. We still know too little about the matter and won't learn more unless the acquisition of a first language be studied as a biosocial process, one of simultaneous neural development, socialization, and enculturation. (See Hebb *et. al.* (1971) for suggestive psychobiological hypotheses on first language learning.) We might have a satisfactory answer if the problem had been treated as one in biological and social psychology rather than in pure (nonbiological and nonsociological) psychology, let alone as a puzzle in the prescientific philosophy of mind. (See Bunge, 1983.)

3.2. *Language, Thought, and Reality*

Regardless of its unknown—though undoubtedly humble—origins, today's human language is unique. Unlike any other systems of signals, or communication methods, human language has become a *general purpose device* (James, 1890, II, p. 356). Indeed it can convey (if suitably enriched when needed) any message we may think of; it serves as a social link (to exchange information and modify other people's behavior) and it is a powerful thinking tool (as well as, occasionally, a cloak to disguise the absence of thought).

Although neurolinguists have found that language and thought are "subserved" (produced) by two distinct neural systems, there is no doubt that these systems are intimately related. (Section 3.1.) There is no speech understanding without ideation, and ideation is in turn greatly facilitated by language. The connections between the two neural systems are neural, hence material, not immaterial connections between two compartments of an immaterial mind. Some such connections are newly acquired (as when we learn to name an object), others are lost (temporarily or forever), and still others change (as when we decide to give a new idea an old name, or an old idea a new name). The set of all such connections can be summarized into a code that pairs thoughts (and images, feelings, etc.) with sound sequences or visual images.

Thought can be encoded linguistically to the point that much of our speech and writing is made up of ready made phrases expressing thoughts we have had previously. This well known fact has suggested several hypotheses concerning the role of language in thinking and behaving. One is that language guides thought and behavior, so that the latter should be explained in terms of the former (Luria, 1961). However, developmental psychologists and psycholinguists (Piaget, 1955; Slobin, 1973; Clark, 1977) have found that the acquisition of language follows that of knowledge: in the child perception, imagination and ideation precede verbal expression. (For experimental evidence against Luria's hypothesis that language regulates behavior see Bloor (1977).) What is true is that (*a*) once a language has been acquired it can greatly facilitate the learning of new ideas expressed or expressible in the language; (*b*) whereas sometimes thought appears to come in the wake of language, usually it is facilitated by the latter, which on occasion replaces it; (*c*) no language can be learned except with the help of perception, feeling, imagination, and ideation.

A second conjecture is that the child is born with "the language of thought", or mentalese, which he then learns to translate into English, Sanskrit, Maya, or what have you. The way he learns to perform such translations is by making hypotheses, testing, and revising them. These hypotheses would be of the form "$L(x)$ is true (in language L) if, and only if, $M(x)$" where M is a predicate in the mentalese repertoire of the child (Fodor, 1975). Clearly, this extreme rationalist view renders the learning of new concepts impossible; also, it is at variance with neuroscience, which shows the cortex of the infant to be poorly organized. (See Smith Churchland (1978) for further criticisms.)

A third view concerning the importance of language is the Whorf–Sapir thesis. In its extreme form it states that language is a world view imposing upon the speaker a particular way of looking at the world and therefore of perceiving and understanding it (Whorf, 1956). This is a form of idealism close to Kant's: it may be called *linguistic idealism* (Ferrater Mora, 1967), and it happens to be false. The language of every society is part of its culture and is determined by its overall level of advancement, in particular its fund of knowledge. A language is not a point of view, let alone a world view: it is subject-matter and ideologically neutral—so much so that one and the same language can serve to express mutually incompatible world views.

If a language lacks a word for the concept of atom, or of theory, this fact may indicate that it belongs to a culture whose members do not know about atoms or theories. But surely some of these people can learn to think and talk about such initially alien objects if they care to. As a matter of fact millions of Indians, Japanese and Chinese have assimilated much of Western culture and many of them have made important contributions to it—to the point that it is no longer correct to speak of 'Western' culture. What used to be given this name has become universal advanced culture, and its achievements can be communicated in many natural languages enriched with mathematics. Whatever expressive shortcomings a natural language may have are culturally conditioned and can therefore be overcome for, by and large, life molds language rather than the other way round. In particular, social status and geographical region determine the dialect the speaker will learn, not conversely. (See Trudgill, 1974.) In sum, the Whorf–Sapir thesis is false. (For further criticisms see Rosch (1977).)

A fourth well known thesis concerning the relation between language and reality is that language pictures the world: every sentence in a language would mirror a fact (Wittgenstein, 1922). A first objection to this thesis is that theories enriched with data, not languages, are supposed to represent the world. (Thus Maxwell's theory, not English, represents electromagnetic fields.) A second objection to the picture view of language is that it ignores thought. Actually we have to do with three different sets of object: facts in the external world, thoughts (brain processes), and linguistic processes (e.g. utterances): recall Vol. 1, Ch. 1, Section 3.2. And the correspondences between these sets are far from simple. In some cases a given external fact elicits no thoughts at all, at other times a single thought, and sometimes a numerous family of thoughts. Whereas some of these are verbalized, others are not; and, when they are, there is rarely a unique way in which they can be expressed. Finally there are thoughts without correlates in the external world, as well as bits of language that correspond to no thoughts at all: see Figure 3.5.

All four above theses concerning the relation between language and knowledge are false and they can be traced back to the theological assumption that wisdom is locked in Scriptures, or writings of alleged divine inspiration. This being so, wisdom can be ferreted out of words

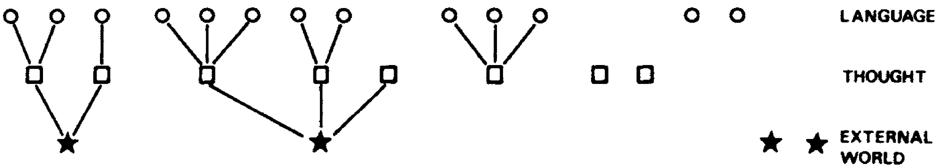

Fig. 3.5. Language, thought, and the external world. Some external world facts are not thought about, hence not described in any language, and some linguistic signs do not stand for any thoughts.

alone, be it by interpreting them correctly (hermeneutics) or by analyzing them (linguistic philosophy). Modern science rejected this approach and turned instead to experiment, theory and action. The later Wittgenstein and his disciples, as well as the German hermeneutic movement, have resurrected the biblical myth that in the beginning was the word—a counter-revolution in philosophy.

Language is both a brain tool and a social tool: it is a means for acquiring or creating knowledge as well as for transmitting it. To be sure not all knowledge is suitably communicated by word: thus motor skills and consequently much artisanal know-how is best learned by imitation. On the other hand all conceptual knowledge is communicable and thus socializable. Hence every major change in the mode of communication is bound to exert a deep influence upon the creation and diffusion of knowledge. In particular writing altered radically the mode of storing and sharing knowledge, as well as the mode of thinking: it made it possible to examine discourse in a far easier and detached way, namely by relying on visual perception. "No longer did the problem of memory storage dominate man's intellectual life; the human mind was freed to study static 'text' (rather than be limited by participation in the dynamic 'utterance'), a process that enabled man to stand back from his creation and examine it in a more abstract, generalized, and 'rational' way" (Goody, 1977, p. 37).

According to Comte every society is bound to go through three stages of development: religion, metaphysics, and science. Others have spoken of primitive and archaic knowledge, philosophy, and science. Finally others have distinguished the following stages: preliterate, literate but prescientific, and scientific. We may adopt the latter periodization, for literacy is a watershed: before it, knowledge could not accumulate beyond the storage capacity of the individual, and it could not be examined in a detached manner as if it were a material object. Besides, only a literate community can build public knowledge stores as well as collective cognitive enterprises characterized not only by their bulk but also by their variety and pace. And only literate peoples can take advantage of the division of labor between those who produce, utilize or diffuse knowledge, on the one hand, and those who handle its externalizations—librarians, book printers and sellers, telecommunications workers, computer programmers, etc.

Literacy was a momentous achievement and yet, like all progress, it had some ambivalent and even some negative effects. Its ambivalent effects were these: (*a*) it gave rise to a new caste, that of scribes, which was (and is) usually in the employment and service of the powers that be—though occasionally some members of it turn against those powers; (*b*) it gave rulers an additional instrument of administration and oppression—but one which could also be turned against them. Literacy had also some negative effects: (*a*) it facilitated the defense of the establishment and its orthodoxy by introducing the categories of holy writ (or body of untouchable belief) and or legal code (or body of rules of conduct) that survived individuals and seemed to have lives of their own above the short-lived and miserable existence of mere humans; (*b*) it reinforced psychophysical dualism, i.e. the idea that thoughts can be detached from thinkers and subsist happily ever after in a world of their own (Plato's, Hegel's, or Popper's realm of ideas). In this respect literacy and, in general, language, is like any other instrument: it can be used for good or for evil.

4. CONCLUDING REMARKS

Learning can be direct (personal) or, by means of communication, indirect (from others). Direct learning can be from experience and, in the higher animals, also from cogitation. Indirect learning can be by imitation or by instruction—or so-called 'self-instruction' with the help of books, journals, or computers. However, in social animals even direct learning, though a brain process, is done in society and largely through social intercourse.

Not only is all human learning social, but all social relations among humans are accompanied by communication of some sort or other. Therefore the study of cognition and language must not disregard their social matrix, and the study of social structure must not underrate communication. This does not entail that we are to blow up the sociality of learning or the informational aspect of sociality. We should not forget that only individuals (living in society) can do the learning, and that all means of communication are primarily means for transmitting knowledge or influencing the behavior of individuals. This caution is in order in view of the contemporary tendency to reduce knowledge, and even social relations, to information flows. There is no information flow unless there is either knowledge to be obtained or transmitted, or action to be elicited or prevented.

Mankind has evolved the most expressive and precise means of communication known to us, namely language. This is not only our most sophisticated mode of social behavior and our paramount means of communication but also a powerful thinking tool, though no substitute for thought and not more valuable than images. Though indispensable to circulate knowledge and extremely useful as a thinking tool, language must not be mistaken for knowledge, just as money must not be confused with production and trade.

This closes our preliminary discussion of the acquisition, use and diffusion of knowledge. Henceforth we shall study particular modes of cognition, in the first place perception.

PART II

PERCEIVING AND THINKING

CHAPTER 4

PERCEIVING

Perception is the basic mode of cognition. Most of the animals capable of knowing get by with only perceptual knowledge. The higher vertebrates also attain conceptual knowledge, which enriches, corrects, and guides perception as well as action.

The best known view on perception is the so-called causal theory of perception, adopted by most empiricist philosophers (in particular Locke (1689)) and all behaviorists (in particular Pavlov (1955)). According to it all our perceptions are caused by external events and more or less mirror the latter. This view is a hypothesis rather than a theory (or hypothetico-deductive system), and it is only partially true. First, it ignores hallucination and illusion. Second, it ignores inhibition, which now obliterates, now enhances the effect of sensory stimulation. Third, it ignores that our expectations, values and hypotheses condition our perceptions. (We indulge not only in wishful thinking but also in wishful seeing.) We need then a truer account of perception, one making room for the creativity of the brain and, in particular, for the intertwining of perception and conception.

The causal theory of perception has been a constant concomitant of epistemological realism. This does not entail that, by correcting it, we have to give up realism. Even though our nervous systems are not passive recorders of environmental events, they do strive to perceive them correctly, and occasionally they succeed in doing so with the help of conception and action and, in recent times, also with the help of artificial sensors and recorders. We do not construct reality every time we look at or think of it. Le Roy was mistaken to assert that *"Le savant crée le fait"*, and so are the anthropologists and sociologists of knowledge who unwittingly follow him believing that they are being faithful to Kuhn's (1962) somewhat ambiguous statements. The student of facts is given not only her brain and the cultural tradition into which she is born but also the very object of her study, namely the world—the only foundation of knowledge. What she is not given is a full understanding and control of her environment. But in a democratic society she is expected to learn something about her surroundings and herself, to make some contribution to the understanding of the world, and to have a share in the control of it.

Perception occurs both at the beginning and at the end of every cognitive process concerning reality: it supplies facts to be accounted for as well as facts testing our accounts of the former. In this sense perception is the alpha and the omega of cognition. But by the same token it does not exhaust the entire alphabet: the remaining letters symbolize so many conceptual operations. One such conceptual operation is the explicit formulation of the problem posed by the initial perceptual data—e.g. What is that?, or Why is that so? Another is the formation of tentative hypotheses designed to solve such a problem. The test of such hypotheses joins conception with perception. Cognitive success lies then not in reducing conception to perception (radical empiricism) or in discarding the latter (radical rationalism) but in the alternation and confrontation of perception and conception.

1. FROM SENSING TO PERCEIVING

1.1. *Sensing*

All organisms detect some environmental changes, but only the animals endowed with special detectors, namely sense organs, may be said to sense them. Thus whereas the octopus can see its immediate environment and discriminate among its components, presumably the sea urchin, which lacks sense organs, only detects changes in stimuli (von Uexküll, 1921).

Sensation is the specific function or activity of neurosensors such as the retina and the taste buds. Neurosensors are ordinarily multicellular systems specialized in detecting stimuli of certain kinds coming from the environment or from other parts of the animal. Like microscopes and photovoltaic cells, neurosensors filter out some (actually most) of the stimuli impinging upon them, and they accentuate the spatial heterogeneities and temporal changes in the environment, i.e. they enhance contrasts. For this reason they are similar to tuned filters (Ratliff, 1965, 1971).

Both the filtering out of stimuli and the enhancement of contrasts are results of inhibition. Thus when looking at a thing our success in seeing it depends not only upon the illumination of the external object but also upon the inhibition of the neurons in the visual cortex surrounding those that have been activated. (Thus, as Leonardo noted 500 years ago, when looking at a printed page you see all the printed symbols at a glance but, in order to make out the words, you must focus on a small region of the page. In modern terms, in order to perceive what you detect you must inhibit your detectors.) The same holds for the other senses, in particular hearing and touch. This feature, lateral inhibition, is a peculiar property of the nervous tissue totally ignored by S-R psychology. It had been discovered by Mach one century ago, later forgotten, and rediscovered by Békesy (1967). From here on the minimal possible psychology is S-I-R, not S-R.

There is agreement that our sense organs are adaptations, i.e. results of genic variations followed by natural selection. However, such adaptation has not consisted in a gradual improvement of all the senses. Thus it is likely that our remote ancestors were capable of hearing, tasting and smelling better than we do, but we seem to be able to see better than they did. In addition to evolution we must take development and training into consideration. Thus a child's sensory discrimination is poorer than a normal adult's, and that of a technician or an experimental scientist (in particular an optician) is far superior to that of a layman.

Even so, our best senses have well known limitations. For example, if a thing moves very fast we see it as blurred or even not at all; and if a multicolored disk rotates rapidly we see only a homogeneous grey patch. And, no matter what the sensory attribute may be, we cannot distinguish without confusion more than about six different stimuli—e.g. visual position, or pitch, or salinity. In other words, our channel capacity is rather poor and is fairly uniform over the entire sensory domain (Miller, 1967). However, sensory discrimination can be educated to attain a remarkable sensitivity in musicians, microscopists, color experts, wine tasters, and other sensory specialists.

The phenomena of filtration, contrast enhancement, and confusion (poor discrimination) show that the vertebrate nervous system is not so much an information processor as a sink. When impinging on the central nervous system some stimulation gets lost in the following ways: (*a*) all sense organs are highly selective filters (e.g. we do not see infrared radiation or hear ultrasound); (*b*) the excitation reaching a point in the nervous system is not propagated but circumscribed (lateral inhibition); (*c*) excitations are usually dampened; (*d*) the various internal and external stimuli often cancel each other (compensation). All this shows that the nervous system is not at the mercy of its external or even internal environment. It is permanently active and it can do its job because of the above properties. In fact filtering cuts out much disturbing excitation, such as the infrared waves generated by our own body. Inhibition improves the signal/noise ratio (e.g. yielding enhanced contrast). Damping protects us from incessant environmental shelling. And compensation discards much useless (together with some useful) information. By all these means the nervous system avoids information overload.

Accordingly the conception of the nervous system as an input-output box describable by a simple systems theory, such as information theory, is basically mistaken. Stimuli do not always excite, and those which do, do not always produce responses. On the contrary, all stimuli produce some inhibitions, and in the higher vertebrates much neural activity has no behavioral issue. (The typical mental activity is of this kind.) Therefore the S-R model is basically false. Worse, it has inhibited the investigation of inhibition and of spontaneous neural activity.

A similar criticism is applicable to the so-called ecological theory of perception (Gibson, 1966, 1979). According to this view, information resides in the environment: the organism picks it up ready made, processes it, and uses it, in analogy with the way it processes food. A first objection to this view is that information does not lie around us: we have to produce it, either by transforming sensation into perception, or by generating it internally (in ideation). Even the information-carrying signals impinging upon our neurosensors, such as the images on a TV screen, have to be "read" by the nervous system before they become information. Secondly, ambiguous figures, such as the Necker cube or some of Escher's *trompe l'oeils*, elicit mutually incompatible perceptions: they do not yield unambiguous information. The subject constructs alternatively mutually incompatible information packages out of one and the same stimulus. Thirdly, the subject, far from being a virgin film, has certain schemata (Bartlett, Piaget, Neisser) that allow her to perceive certain things rather than others, as well as to explore her environment searching for certain stimuli (e.g. moving objects) in preference to others.

In sum, the animal detects (some) environmental changes impinging upon it (i.e. it senses stimuli) and perceives ("interprets") some of them: it never picks up ready made information lying about it. Information about a stimulus equals perception of the stimulus. An unperceived stimulus carries no information; an incorrectly perceived stimulus carries wrong information; and an ambiguous stimulus elicits the generation of mutually incompatible pieces of information. In all such cases *information is generated by the organism* not just received and processed by it. Hence we should speak of *stimulus pickup and transduction* instead of *information pickup*, and we should drop the simplistic assumption that information theory is the answer to the problem of perception. But we are encroaching on the subject of the next subsection.

To conclude this subsection. The neurosensors supply the raw material of our knowledge of the external and internal worlds. Without them we would know nothing, with them alone we would know nothing either. This is not philosophical dogma but a result of empirical research. In fact (*a*) subjects cut off from the world, in experiments on sensory deprivation, become spatially and temporally confused, and they start to hallucinate; and (*b*) subjects with their neurosensors intact but damages in the sensory areas of their brain cortex are incapable of processing the incoming stimuli: they can detect but not perceive (agnosia).

1.2. *Perceiving*

Physics and chemistry explain what happens in the eye from the moment light enters into it till it strikes the rods or cones in the retina. (Hearing is parallel.) From then on neurophysiology and psychobiology must take over. Thus the containment of the excitation, i.e. the inhibition of the cells surrounding those that are excited, is a typically biological process. The continuity of the visual world despite our blinking every few seconds may be an effect of a neural inhibition generated by the brain, that diminishes the effect of the blinks (Volkmann *et al.*, 1980). The discarding of small differences (as in pattern recognition) is the job of specialized (feature) cells in the primary visual cortex. And our perceiving distant objects almost as large as close ones, despite the fact that they project a smaller image on to our retina, is presumably a result of the activity of large neuronal systems in the secondary or tertiary visual cortex. All such phenomena illustrate the difference between sensation (or recording) and perception (or elaboration of sensation).

Whereas sensation is localized in the neurosensors, perception is distributed throughout large regions of the brain. Recently developed techniques for imaging and measuring local cerebral blood flow, metabolism, and other processes, allow neuropsychologists to locate the areas of the brain that are activated by a specific sensory stimulus. (Cf. Phelps *et al.*, 1981; Greenberg *et al.*, 1981.) One result is that the images of the brains of subjects given somatosensory, visual, or auditory stimulation are quite different. Another is that they have a significant overlap, suggesting that some neuronal systems are activated by sensory stimuli of any type. This may explain why our perceptions are strongly colored by our memories and expectations and why they are accompanied by some movement or other.

We have no direct knowledge of the external world, for what is sensed is some event at the tip of a sensory nerve. The attribution of this even to an environmental item is a brain construction—either a perception or a hypothesis—and one that is sometimes correct and at other times incorrect. Thus a dog wounded by a stick does not snarl at its wound but at its attacker. We share with many animals "the power of imputing otherness and beyondness" (Lovejoy, 1929). The constructive nature of perception is further shown by the fact that we do not have to see a familiar thing in its entirety to recognize it: seeing only part of it, at a given angle, often suffices. (If it did not we would never recognize anything, for we cannot see any thing in its entirety.) In other words, neurosensors sample (and analyze) clusters of features, which are completed and integrated by the brain during perception.

Perception integrates sensation, is accompanied by behavior (e.g. eye movement during scanning), and is guided or misguided by conception. Indeed it has been shown experimentally that, if motor activity is impeded, e.g. by immobilizing the subject's eyes or limbs, then visual perception stops altogether. And if a subject wears a prism that reverses right and left, or top and down, and moves around, eventually the world "rights itself" for him: his plastic brain establishes new connections. In short, the way we perceive depends on the way we behave and conversely. (Cf. Taylor, 1962.)

Likewise what we perceive depends not only upon the stimulus object but also upon our knowledge and expectations. In short, in all likelihood there is no pure perception untainted by ideation and behavior. This result of recent physiological psychology had been anticipated by a number of philosophers. In particular Bacon, Kant and Whewell held that the way we perceive an external object is partly determined by our knowledge of it. Thus when I report that I am seeing Venus, I am drawing on my fund of knowledge: another person presented with the same celestial object might claim that he sees a star, a UFO, or an angel. This being so, it is very likely that our ancestors, even the recent ones, did not perceive the world exactly as we do. However, it was roughly the same world as ours.

Consider listening to speech or reading. Normally "concrete" words, such as 'run', trigger images, whereas "abstract" words, such as 'commutativity', trigger concepts or symbolic diagrams representing concepts. And when hearing or reading a new word either we form neither image nor concept, or we guess the correct image or concept from the function the word discharges in the sentence: i.e. we conjecture its meaning from certain contextual clues. In short, speech perception and reading are highly constructive processes involving sensing, perceiving, imagining, remembering, conjecturing, and expecting. (See Carterette and Friedman (Eds.), 1976.) The reading of musical scores, diagrams, graphs, blueprints, and the like, must be parallel.

Percepts do not appear automatically and immediately upon sensory stimulation, but are constructed or synthesized (Selfridge and Neisser, 1960). This constructive view of perception has been confirmed by neurophysiology. In fact, we know from the work of Hubel and Wiesel (1962), Evans and Whitfield (1964), and others, that certain cortical cells specialize in recording single features (e.g. edge, inclination, or color), and that their output is synthesized by further neural systems. We also know that there are no isolated neural systems, so it is conceivable that the activity of the perceptual synthesizers is controlled by memory, expectation, and ideation. See Figure 4.1.

Throughout the history of philosophy and psychology two major views on perception have clashed: those on perception as recording (or passive models) and as constructing (or active models). Naive realism and empiricism have held the former, whereas idealism has held the latter. The passive models are the slate and the filter: according to them all the nervous

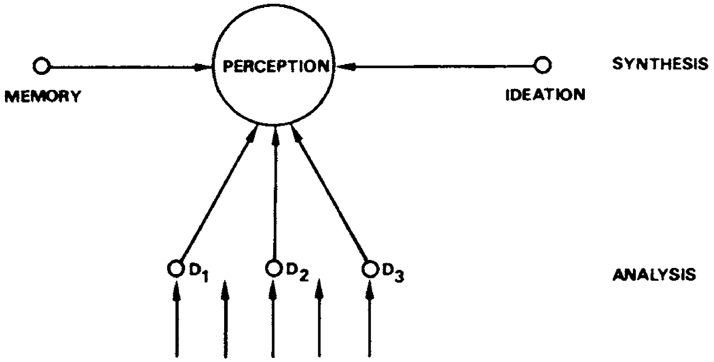

Fig. 4.1. Cells D_1, D_2 and D_3, of different kinds, respond selectively to different features of one and the same stimulus, and their outputs are synthesized by a neuronal system (the perceptor). Some of the features of the stimulus are either not detected at all or suppressed. The synthesis is not a neutral summation but is influenced by the current state of the whole brain, in particular its memories and expectations. Thus when we say "I know this girl" when meeting a particular girl, we mean that we have recognized her: our perception of her is "colored" by our memories of her and perhaps even our expectations about her.

system does is to record and select the incoming stimuli. A deterministic automaton with or without output would be a good mathematical representation of such models.

Obviously, no passive model harmonizes with neuroscience, in particular the findings about lateral inhibition and the spontaneous ongoing activity of neurons and neuronal systems, in particular the integration of the outputs of specialized detectors (recall Figure 4.1). These findings support on the other hand some active or constructive model, according to which perception is a brain activity resulting from the joint action of input signals and internal processes. As a matter of fact it has been known since Helmholtz (1879) that the senses, far from giving us a *picture* of the world, give us only *signs* of it, which signs must be "interpreted" by the brain to become cognitive items. In short, we do not just copy or reflect but construct. However, this does not endorse idealism: we do not construct the world but only map it.

Every animal is equipped not only with a number of sensory systems but also with certain predispositions or propensities to use such systems in certain ways rather than others. Thus we are predisposed to paying attention to moving objects and shrill sounds; to listen to and imitate human speech in certain languages rather than others (similarly most song birds imitate the song of their conspecifics even when they are exposed to the song of birds belonging to other species, or to music); we notice items of certain kinds more readily than others (e.g. expecting parents tend to see pregnant women and babies everywhere), and so on. These perceptual propensities are inherited or acquired properties of our brain and they develop with it: they allow us to have certain experiences and are in turn modifiable by the latter. Psychologists call such predispositions perceptual *schemata* (Bartlett, 1932; Piaget, 1952; Neisser, 1976).

A perceptual schema is neither a thing (e.g. a neuronal system) nor a process in a thing. It is a cluster of properties of a neuronal system and, more particularly, a bundle of propensities for it to act in a certain manner in the presence of external or internal stimuli of a certain kind. Presumably such propensities can be quantitated as probabilities, so that all models of perception should be stochastic models. However, this is just conjecture: we still do not have adequate models allowing us to explain how a person in a certain state sees a chair as a piece of furniture, and when in a different state as a weapon or as a piece of firewood. The most sophisticated models of perception, those of Hoffman (1966), are not stochastic but use Lie groups, and they do not involve any neuroscience. A characteristic hypothesis of such models is that a global pattern is the result of an iteration of Lie operators—rather than, say, the activity of a neuronal system activated by a number of sensory analyzers or detectors.

Adequate models of perception can be produced only by neuropsychology (or physiological psychology): they will not come from pure psychology, let alone from philosophical psychology, which has been at it for over two millennia without ever getting hold of that which does the perceiving, namely the central nervous system. A good example of the failure of armchair speculation on perception is the "new theory of perception" advanced by Brown (1977). This view is claimed to elucidate Hanson's idea that scientific percepts are theory-laden. (Actually this idea goes back to Whewell, who took it from Kant, who knew about Bacon's *idola.*) The gist of this view is that the distinction between *seeing* (e.g. a shadow) and *seeing that* (e.g. that the shadow has been projected by a person) is that in the second case the observer takes in "the meaning of the observed situation" (Brown, 1977, p. 87). The author calls this 'significant perception' in contrast with sheer perception (actually sensation). But of course there is no *theory* proper (i.e. hypothetical-deductive system) here. There is not even analysis, for Brown does not elucidate the key notion of "meaning of a situation". And there is no novelty, for the whole thing boils down to the old finding that we perceive what we are prepared to perceive. The challenging task is not to use ordinary language expressions to describe once more the difference between untutored sensation and educated perception, but to build a psychobiological theory couched in mathematical language.

Understandably, most of the research in perception has been concerned with vision. (If we dwelt in deep caves we would presumably have specialized in tactile and auditory perception.) However, not all perception is of some external object: there is also perception elicited by bodily processes. Thus we perceive the pressure of one hand rubbing the other, and we perceive (painfully) the thorn in the toe or the ulcer in the duodenum. Besides, the brain can generate perceptions that have no stimulus object, whether external or internal: such are hallucinations and imaginations. (The only difference between these two is that the former falsely imputes some external stimulus object.) We can imagine pictures, sounds, bodily processes, and feelings. We can do so at any time, while awake or in sleep, working or daydreaming, in normal circumstances or under the action of drugs or of hypnosis. (There is no such thing as a hypnotic trance: the good hypnotic subject is highly suggestible and imagines whatever is suggested by the hypnotizer: Barber and Wilson, 1979.)

Imagination is a mode of cognition without which nothing great is ever achieved in any field. True, the products of imagination must be checked for truth or efficiency unless we are bent on creating a work of art. But the same holds for ordinary perception and conception as well: we are not to trust any single cognitive operation. Moreover such checking is never automatic and infallible: it takes a lot of imagination to produce firm evidence for or against the works of imagination. Only the empiricist obsession with empirical data could make us forget for a moment that the most valuable data are those produced with the help of imaginative means such as sophisticated experiments inspired by sophisticated theories. Scientists and technologists do not shun imagination: they cultivate it and keep it under control.

Imagination takes part also in the intuitive or ordinary knowledge of other minds known as empathy. Empathic understanding, which we share with many animals, is nothing but imagining what goes on in someone else's brain, or "putting oneself in the other's shoes". It is compassion, coperception and coideation. Empathy uses (ambiguous) clues and (fallible) conjectures relating overt behavior to mental states, e.g. the shedding of tears to sadness, and the shuffling of feet to embarrassment. Like every mode of perception, empathy is fallible: the illusion of infallibility comes from our noting its hits and disregarding its misses. "Lovers, who are notoriously supposed to be empathic, as frequently seem to misunderstand as understand each other's motives and acts; and what they normally do, perhaps, is wilfully misunderstand their existing differences, so that they create an illusion of unanimity of opinion and feeling" (Ellis, 1963, p. 119).

What about space and time: are they perceptible? Although many psychologists write about the perceptions of space and time, these are imperceptible: only (some) events are perceptible (under special circumstances). What we can perceive is not space but events that hold spatial relations; nor do we perceive time but events in temporal relations. Thus we hear one noise to the right of another, and perceive the former before the latter, but "to the right" is just as imperceptible as "before". In general, we perceive neither things nor properties nor relations: we perceive only some events, which are changes in properties of things or relations among things. If there were changeless things we would not notice them.

Finally, can we perceive external objects without the help of the senses:

i.e. is there extrasensory perception (ESP)? In the context of traditional psychology, which ignores the nervous system, this question must be regarded as open, for one might hope (or fear) to get eventually some firm evidence (other than statistical mistake or deception) for the hypothesis of ESP. Likewise before the nature of meteorological events was understood one could hope or fear for a storm to strike out of the blue. We now know that the perception of a stimulus object (unlike imagination and hallucination) is the terminus of a process that starts at some nerve ending or other, and ends up in a secondary or tertiary sensory area in the cortex. This being so, clairvoyance and other alleged ESP phenomena are as illusory as running without limbs or digesting without guts.

It is a firm finding of physiological psychology, and a principle of our epistemology, that all external perception is mediated by some sensory system. Put negatively: there is no ESP and there can be none. In particular there is no direct communication among animals at a distance: all communication proceeds *via* physical signals (light, sound, touch, etc.). And what mind reading there is consists in perceiving and interpreting the movements or signals produced by another animal. Thus you are reading my mind as you read these lines.

2. OBSERVING

2.1. *Direct Observation*

There is an important difference between spontaneous and directed perception, or sheer perception and observation. In the former case we look *at* things, in the latter we look *for* them. Directed perception, or observation, is purposive, active, and deliberately selective. A dog and a human being watching the passing scene are onlookers; a dog looking for a bone, and a human being looking for a friend, are observers. The difference is one of psychological "set" (*Einstellung*): different neuronal systems are presumably involved.

Because observation is purposive and selective perception, it can be educated. (Recall Leonardo's injunction to his students: *Saper vedere.*) In fact the training of a young hawk, a tiger cub, or a human infant, are largely education in observation skills: in focusing on certain things or traits while disregarding the rest, or enhancing the effect of certain stimuli while inhibiting others. (Békesy (1968) stated that "a good observer is an observer who learns to inhibit". But so is an observer incapable of perceiving due to bias or to unwillingness to face reality. Thus Tolstoy's Karenin "was unwilling to see anything and so saw nothing".) There is little doubt that our children, who are exposed from birth to a ceaseless stream of pictures and noises, are better lookers but worse listeners than our fathers. In the case of humans this education is not only sensory-motor but also intellectual. We perceive almost exclusively that which we have been trained to perceive (including self-training). If our brain has been soaked since childhood with witches, devils and conspirators, we are bound to look for them and likely to find them. If on the other hand we have had the benefit of a scientific or technological education we shall tend to look only for concrete things that can be accounted for in naturalistic terms.

Two persons, a farmer and a scientist, see a brilliant thing now hovering above them, now moving swiftly away, and neither can identify it immediately. If the farmer has heard about angels or UFOs (first "seen" in 1947), he may believe he is seeing one of either. The scientist, on the other hand, is likely to identify the object as an aircraft, a plasma, or Venus. Philosophical subjectivists notwithstanding, both subjects deal with the same object perceived differently. This holds not only for brilliant flying objects but for almost everything: people with different backgrounds, cognitive attitudes, and value systems, are bound to see the (only) world there is in more or less different ways.

Some philosophers, in particular Whewell (1847), Duhem (1914), and Hanson (1958), have stated that experiences like the above show that observation, far from being neutral or uncontaminated by theory, is penetrated by it. (Hanson introduced the expression *theory-laden*, which is incorrect, for most observers do not know any theories proper. The expression *hypothesis-driven* seems preferable.) There is a grain of truth in this: we do tend to observe what we expect to perceive, we often do miss what we do not anticipate to perceive, and all our expectations are determined by our fund of knowledge (and superstition) as well as by our value system (or interests). However, that grain of truth should not be puffed up to the point of epistemological relativism and subjectivism. The observations on the brilliant flying object reported by the farmer and the scientist are not equally correct: they are mutually incompatible, both can be checked for objective truth, and it so happens that the checks favor the scientific version.

True, observation is hypothesis-driven, particularly in the sciences, because it is selective. The myth of immaculate observation is all but dead, even in predominantly observational disciplines such as ethology (Hinde, 1970; Beer, 1973). But, if scientific, rival hypotheses are checkable. And, once checked (against data or theories or both), they are bound to be shown unequal in worth (truth value, generality, or depth). The same holds for data: many of them can be replicated, and all of them are (in principle) checkable by different means or methods. Consequently even if all of them are hypothesis-driven, many of them are *invariant with respect to changes in the driving hypothesis*. So, such data are in effect uncontaminated by any particular hypotheses. This is the case with many data stemming from direct observation, i.e. observation unaided by any instruments, such as those gathered by a census bureau. On the other hand indirect observation, i.e. observation conducted with the help of scientific instruments, is not only driven by hypotheses but is also hypothesis-dependent, i.e. its worth depends in part upon the hypotheses involved in the design and operation of such instruments. We shall return to this in the next subsection.

What is the epistemic value of observation? According to empiricism all and only observation supplies genuine knowledge: i.e. observation is necessary and sufficient for it. Epistemological analysis shows that observation, though necessary, is not sufficient, for all observation is hypothesis-driven, and all indirect observation is hypothesis-dependent. Thus finding a fossil bone is not, in itself, a scientific discovery: many people had found, and discarded or misinterpreted, fossil bones before evolutionary biology made it possible to "interpret" them as remains of organisms that lived long ago. An empirical scientific discovery is a finding together with a theoretically plausible account of it. Hence two rival accounts of one and the same finding must rate as different discoveries—at most one of which can be correct. Thus Columbus and Vespucci, though interpreting roughly the same geographical findings, made different discoveries: in fact only Amerigo Vespucci discovered America. Likewise although the ancient Greeks knew about amber and loadstone, they did not discover electricity or magnetism; and the discoverers of DNA did not realize that it is the genetic material, and so did not discover that DNA is the carrier of heredity.

Observation, though insufficient, is necessary for genuine knowledge of fact. True, we cannot observe directly neutrinos or synaptic boutons, any more than live dinosaurs or prehistoric events. But we do make certain observations of related things that motivate and check the hypothesis of the current or past existence of unobservables. On the other hand there is no observational evidence for the hypothesis that there are disembodied entities, such as ghosts and ideas in themselves: hence this hypothesis does not count as genuine knowledge. The need for observation in gaining factual knowledge is a tacit postulate of science and technology. (Even the highest level scientific theories, such as quantum mechanics, contain constants or parameters whose values can be known only through measurement. And all measurement involves, at some point or other, direct observation.) Therefore we incorporate that principle into our epistemology: *All knowledge of factual matters consists of, or involves, some direct observation.*

The historical sciences, such as cosmogony and geology, archaeology and human history, are not exempt from this condition. True, historians cannot observe events in the remote past: most of their observations are limited to remains, such as tools and written documents. They must conjecture the possible use of tools and, if they proceed scientifically, they will make replicas and try them out; and they must be able to interpret the documents and try and check them with other findings. In all cases, regardless of the amount of speculation historians may embark on, they have to make some contact with observation if they wish to substantiate their hypotheses. The same holds for all the other historical sciences, from cosmogony to evolutionary biology: there is always some observation involved in them, whether at the beginning or in the middle or at the end of a research cycle. A field of inquiry that involves no observation at all is either strictly formal (i.e. logical, mathematical or semantical), or purely speculative—and therefore nonscientific.

2.2. *Indirect Observation*

Not all facts are directly observable. By far the greatest number are not: think of electrons or quasars, of genes or nations, of atomic collisions or historical events, of extinct organisms or neural processes. All such facts go beyond appearances and therefore constitute a glaring refutation of phenomenalist epistemologies and metaphysics.

Suspecting that reality encompasses more than appearance, scientists have devised literally thousands of means for extending the reach of our senses. Strictly speaking only a few such means—e.g. the scale, the microscope and the telescope—extend the scope of the human senses. Others, such as the magnetometer and the pH meter, the voltmeter and the interferometer, the Geiger counter and the EEG, are not extrasensitive eyes, ears, tongues, or skins, but tools without biological precursors. However, all of them supply directly observable facts, such as clicks,

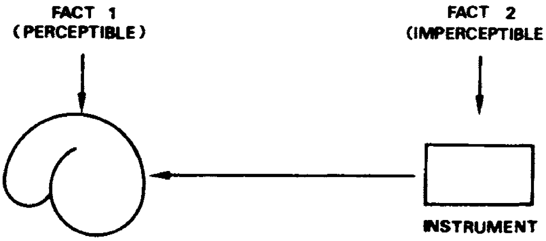

Fig. 4.2. Direct and indirect observation.

coincidences between pointers and divisions on a dial, or computer printouts. The mode of inquiry employing such means may be called *indirect observation*. See Figure 4.2.

A short and haphazard list of such means should show how much farther than our senses they go, as well as how hypothesis-dependent they are. Radiotelescopes are indispensable to study radiostars. Astronomers hope (or dread) to discover black holes either by looking for very luminous stars (binary pulsars?) that seem to revolve around nothing, or by observing the radiation emitted by objects in the process of being swallowed by black holes. Neutrino detectors allow one to "look" into the interior of a star, where they are produced, for starlight comes mostly from the thin stellar atmosphere, and neutrinos can traverse it almost undisturbed. (Incidentally, such observations have recently upset the accepted theories of the structure of stars.) Field-ion microscopes and scanning transmission electron microscopy produce direct images of individual medium to heavy atoms and molecules. (The classical techniques supply only images of average structures.) And there are several techniques for detecting what goes on in the living human brain (e.g. microelectrodes and EEG) and even for imaging such processes—e.g. computer assisted tomography (CAT scan) and positron emission tomography (PET scan).

As with direct perception, instrument assisted detection is of events or changes, and the detection itself is a change in a thing, namely the detector. To be sure the thing detected may appear to be in a stationary state, as is the case with the printed page you are looking at right now. But this is only appearance: in actual fact this page, while legible, is being bombarded by myriads of photons, some of which are absorbed, the rest reflected, and all of which affect this sheet in some manner, e.g. by warming it up and speeding up some chemical reactions in it. In short, only events are detectable.

Every means of indirect observation is conceptual as well as material, for it involves not only a material instrument, such as a scale or an amplifier, but also a set of hypotheses employed in its very design and operation. Thus, the detection of radio waves employs electromagnetic theory; X-ray and neutron crystallography involve not only pieces of apparatus but also the theory of diffraction; electrophysiology uses not only electrodes and meters of various kinds but also scraps of physical and biological theories. In many cases the theory itself suggests the very existence of the thing to be detected as well as manners of detecting it. (Thus a certain technique for detecting the elusive neutrino is based on calculations showing that, when the nucleus of gallium 71 absorbs a neutrino, it turns into the nucleus of germanium 71, a different element.)

Without such theoretical components the raw data supplied by indirect observation would be unintelligible and therefore useless, for they bear no obvious relation to the facts that are being observed. Thus a layman would not know what to make of a sequence of clicks in a Geiger counter, or of an X-ray diffraction pattern, or of a collection of spots on a sheet of chromatographic paper. Every indirect observation requires an "interpretation" of the data, which "interpretation" consists of hypotheses about the nature of the events of interest and their interaction with the detector. This intervention of hypotheses in observation is not limited to natural science, medicine and engineering, but occurs in all fields of research. Thus sociologists use social indicators, and economists economic indicators, to detect changes in society, and prehistorians examine artifacts, bones, and inscriptions to "read" the evolution of mankind. In all such cases certain hypotheses—that will be called *indicator hypotheses*—link the available data with the events of interest. (More on indicators in Ch. 11, Section 2.2.) In short, every means of indirect observation, be it of microevents such as atomic collisions, or of macroevents such as economic crises, involves a theoretical component—or, as an empiricist would say, is "contaminated" by theory.

Indirect observation has advantages and disadvantages with respect to direct observation. The advantages are obvious: (*a*) it enables us to go far beyond appearance; (*b*) because it employs impersonal instruments free from conceptual or moral bias, and yielding data that can be perceived by all competent observers, it is less subjective than direct observation. The disadvantages are equally evident: (*a*) some instrumental probes disturb the probed object (particularly in microphysics), and all instruments are likely to produce "artifacts", i.e. effects of their own (e.g. halos and stains) that the observer may mistakenly impute to the observed object; (*b*) the data resulting from indirect observation are just as fallible as their theoretical components. Not surprisingly, if one wishes to get more one must be prepared to pay more. However, the cost (i.e. error) may be lowered with improved instrumentation and theory.

As for bias caused by wishful thinking or dishonest intention, indirect observation is neither more nor less susceptible than direct observation. One can lie not only in reporting sightings with the naked eye but also with a camera—e.g. by changing the sequences of frames, or taking pictures from appropriate angles or under suitable illumination—or by splicing tapes or simply by selecting the favorable data and eliminating all the others. However, it is obvious that lying with cameras (or meters or computers) goes down better than without them. Hence the methodological and ethical precautions are more necessary in the laboratory than in the field or the street, the more so since all results of indirect observation must be doctored in some way or other.

Advanced science has little use for raw data: the latter must always be corrected for a number of effects, and sometimes (as in the case of outlying figures) thrown away altogether. The line between standard data correction and finagling, between honesty and dishonesty in reporting results of observation, is not always a clear one. Newton has been accused of smudging astronomical data and Mendel of ignoring certain results of his hybridization experiments. Morton has been shown to shift criteria, and omit or miscalculate some data on cranial capacity for harboring "an a priori conviction of racial ranking" (Gould, 1978); and Millikan discarded some values of the electric charge of the electron for failing to square with his hypothesis (since amply confirmed) that all electrons have the same charge (Holton, 1978). In all these cases preconceived ideas—sometimes true, at other times false—had distorted the presentation of data. Nor are such cases exceptional: they occur all the time in ordinary life and in the laboratory. Thus if we are used to seeing A's but not B's under certain circumstances, or if we assign A's a greater probability or utility than B's, we may miss the latter when they occur or confuse them with A's—or may be inclined to report only A's for fear of being taken for fools. (For an experimental study of biasing factors in discrimination problems, see Swets (1973).)

Not all observers are equivalent in all respects—*pace* Ziman (1979). Therefore we should not expect that different observers will always produce the same reports on one and the same group of facts. Two observers may be inequivalent because they are not in the same state of motion, or because they use different equipment, or operate the same equipment in different ways, or under different circumstances. Or they may be inequivalent because they handle their data (e.g. round off, average, or discard figures) in different ways. Or because one of them is gifted or lucky enough to notice something missed by the other, or because one of them is wedded to a certain hypothesis whereas the other is indifferent to it. (Recent examples of the effect of theoretical bias have been seen in the search for gravitational waves, black holes, and quarks.)

Even the most competent and lucky of observers is faced with the inherent limitations of every means of observation. All optical instruments have a limited resolving power due to the diffraction of the impinging light. Electronic and protonic microscopes possess a far greater resolving power but have their own limitations. Astronomers are up against the limits of their instruments as well as of the observation sites: clouds and turbulent currents, not to speak of smog, will produce a diffuse and constantly fluctuating image because of the variation in the atmospheric refraction index. Obviously, such limits to the accuracy of observation are limits to knowledge. However, some such limits can be overcome in principle and possibly in practice. For example, telescopes installed in artificial satellites or on the Moon will be free from atmospheric nuisances, and all kinds of electric meters are essentially free from thermal noise when working at extremely low temperatures.

We summarize the above discussion on the reach and limits of observation in the following *postulate. For every fact f* (thing or event) physically accessible to cognitive subjects (*a*) *there is* (actually or potentially) *a means m of observation such that f has observable traits relative to m* (i.e. such that *m* helps detect some properties of *f*), *but (b) there is no means allowing one to observe all of the traits of f with complete accuracy.* In short, the means of observation can all be improved but never be rendered perfect. (*Notes*: (*a*) the physical accessibility condition excludes most events in the remote past, as well as all future events and those outside the observer's light cone; (*b*) the limits on observation have nothing to do with Heisenberg's indeterminacy inequalities, which only limit the applicability of the classical concept of a corpuscle.)

3. MAPPING REALITY

3.1. *Perceptual Mapping*

Perceptions, whether spontaneous or sought, do not pile up haphazardly but tend to get organized into systems. Such systems of percepts are called *cognitive maps* or *internal representations*. Some of them represent our environment (*environmental maps*), others our own internal states (*body maps*). These maps are continually updated, they summarize our perceptual knowledge of our surroundings and of ourselves, and in turn they help us take care of ourselves, move around, and act: see Figure 4.3.

We do not know exactly what animal species are capable of forming perceptual maps. All we seem to know is that, in order to map or model its surroundings, an animal must possess a nervous system capable of (*a*) *analyzing* or breaking down into distinct units whatever it perceives, (*b*) *recognizing types* or kinds into which such units can be grouped, and (*c*) *organizing* what it perceives into a whole, i.e. synthesize or integrate the products of analysis and type recognition. Presumably, it takes a rather complex nervous system to accomplish all this—say, that of a fly at least—but we do not know exactly what it takes.

According to psychoneural dualism, cognitive maps are immaterial: they are "in the mind". So, by hypothesis subhuman animals would not be entitled to forming cognitive maps. On our biological perspective a cognitive map is a pattern of neural activity in perceptual and motor centers. In particular, it has been conjectured that the internal representation of an object seen by a normal human subject is a sort of ring formed by sensory memory traces and motor memory traces (Noton and Stark, 1971). As a subject sees a thing for the first time, she forms a scan

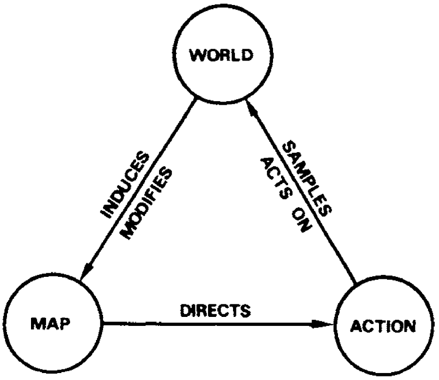

Fig. 4.3. Cyclic model of perception (adapted from Neisser, 1976, p. 112). External objects stimulate the formation of cognitive maps in the brain. These in turn guide locomotion, exploration, and other activities that modify the environment, which changes call for revisions in the cognitive maps, and so on. Caution: both maps and actions are part of the subject, and while both must be conceived as biological processes, the world is a thing.

path of that object. This scan path consists in a chain composed by a visual feature followed by the eye movement required to reach the next visual feature, and so on. When the subject encounters the same object again, she recognizes it by matching the incoming visual stimuli with the "feature ring". Thus once constructed each such ring guides the future perception of similar objects. Each subject constructs her own feature ring, which is fairly permanent. This hypothesis may not be accurate but it matches the available experimental data—particularly all the data concerning the strong linkage between perception and motor behavior—as well as the general psychobiological orientation. It is incompatible with psychoneural dualism—a definite virtue in our view—as well as with the Gestalt hypothesis that internal representations are built in one piece and instantly.

(One way of elucidating the general concept of a cognitive map is as a function from some events in the perceptual field into neural events. More precisely, consider a concrete thing m and take the set M of events happening in m at a certain level L of discrimination—e.g. the collection of all the photons of a certain frequency bouncing off m. Further, call M_L the subset of M formed by the events above a certain level L of discrimination. Then a *cognitive map* of the thing m is a function f from a subset P_L of M_L to a set N of neural events in some subject, i.e. $f: P_L \rightarrow N$, that preserves some of the relations and operations among members of P_L. A perfect cognitive map of m is of course one that (*a*) mirrors every event happening in m, i.e. for which $P_L = M_L$, and (*b*) preserves all of the relations and operations in M_L. We may safely assume that no such perfect map is possible.)

Obviously, the cognitive maps of different individuals, even of the same species, are not identical: each of us perceives herself and the world in her own way. Still, there must be commonalities due to our common ancestry and our shared environment. In general, the individuals of each animal species would seem to map their surroundings in a species-specific way: the octopus in one manner, the owl in another, and so on, as proposed by Uexküll (1921). (Actually Uexküll held that each animal *constructs* its own environment in a species-specific way. This is either sloppy language or subjective idealism. All we do is map our environment, and use such maps to navigate in it and modify it. More on this subject in Ch. 15, Section 2.2.)

In the recent psychological literature the expression 'cognitive map' is usually understood in the restricted sense of a *spatial* map or schema allowing an animal to orient itself in ordinary physical space. Thus O'Keefe and Nadel (1978) have conjectured that all mammals are born with a framework, located in the hippocampus, where they can store all the information concerning places and spatial relations that they gather in the course of their lives. They further conjecture that, "When there is a mismatch between some sensory input to a place representation and the predicted sensory input, a set of *misplace* detectors is triggered, the output of which activates and directs the motor systems involved in exploration. The behavior is directed towards the incongruence and new information can be incorporated into the map as a result of it" (p. 94).

That some animals form spatial maps of their environment, and that such maps guide much of their behavior (approach, avoidance, exploration, etc.), seems beyond reasonable doubt. What may be disputed is the thesis of Descartes and Kant, revived by O'Keefe and Nadel (1978), that all mammals are born with a *Euclidean* framework. In fact it has been known for some decades that (*a*) none of the various perceptual (visual, auditory, tactile) geometry is Euclidean—e.g. some parallel straight lines are seen as curves, whereas some curves are perceived as straight parallel lines; (*b*) children learn rather slowly, when at all, the "facts" of Euclidean geometry. Luneburg (1947) had proposed that visual space has a constant negative curvature, i.e. is Lobachevskyan. Battro *et. al.* (1976) have challenged this thesis on experimental grounds, holding instead that visual space has a variable curvature: it is sometimes positive (elliptical geometry), sometimes negative (hyperbolic geometry), and occasionally null (Euclidean geometry). As for the development of geometrical ideas, we know now that newborns move their heads to locate sounds and sights, so they do have some inborn spatial framework. But we also know, from Piaget's studies,

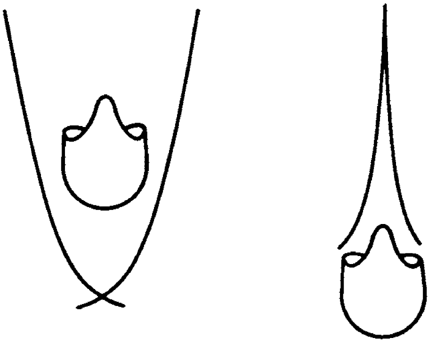

Fig. 4.4. Natural perspective is curvilinear. If asked to trace an avenue or parallel straight sides, the subject imagines curved lines. And if he looks at straight rail tracks he does not see them converging in straight lines but as branches of a hyperbola (Battro, 1979). Curvatures in drawing greatly exaggerated.

that this framework must be rather poor, for the triangle inequality does not appear normally before age 11, and even then only among half of the children (Piaget and Inhelder, 1967). Besides, our natural (untrained) perspective is not rectilinear but curvilinear (Battro, 1979): see Figure 4.4. In conclusion, we are not born Euclidean—or Riemannian or Lobachevskyan. If we did, geometry would not have been such a recent acquisition, and its teachers would have a far easier task.

3.2. *Appearance and Reality*

At birth we have only our perceptions to go by, so presumably we are born phenomenalists: only reflection upon our experience, together with education, turns us gradually into realists. At age 2 we may still reach for the Moon, but by age 4 we have already sobered up. The very young child presented with two things of the same volume but very different shapes, such as a ball and a pencil, tends to judge incorrectly their sizes: he sticks to appearances. Only the child who has attained the "concrete operational stage" tends to recognize the conservation of matter underneath changes in shape, color, and other appearances (Piaget, 1976a). The same holds for adult trained chimpanzees (Woodruff *et al.*, 1978).

We never see the world exactly as it is. For one thing we fail to perceive stimuli below a certain threshold and above a certain ceiling. For another we tend to inhibit most sensations. Thirdly, our bodily state changes from one moment to the next, so that a constant external stimulus is transduced now in one way, now in another. Fourthly, our neurosensors are such that "Humans do not experience the world as it is but as a power function of what it is" (Thompson, 1975, p. 239). This cryptic albeit true and profound statement may be understood as a verbalization of either Stevens' psychophysical law or Thouless' index. The former states that the perceived or apparent intensity of a sensory stimulus is a power function of the physical or objective stimulus. And the Thouless index relates the real and the perceived (apparent) sizes of a visual stimulus object, as well as the projection of the latter on the retina: see Figure 4.5. In sum, pure (sensory-motor) experience yields appearance not reality. If we wish to attain reality we must go beyond perception, into conception and action.

The perception of a fact is called a *phenomenon* or *appearance*. (In ordinary language 'phenomenon' is equated with 'fact': beware of the imprecisions of ordinary language.) There are imperceptible facts but there are no phenomena without sentient organisms. Appearance, then, is an

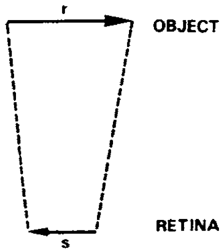

Fig. 4.5. The Thouless index: $i = \log(p/s)/\log(r/s)$, where p is the perceived or apparent size of the stimulus object of size r, whose projection on the retina is s. By algebraic manipulation we obtain $p = s(r/s)^i$. If $p = 4$, then $i = 1$; and if $p = s$, then $i = 0$.

evolutionary gain: it emerged together with the first animals equipped with nervous systems. Before them facts appeared to nobody: there was no appearance, there was only reality.

Phenomena are facts of a special kind, namely facts occurring in nervous systems. So, *phenomena are real.* Consequently there is no opposition between appearance and reality. My seeing the Moon larger on the horizon than overhead is a fact no less than the two positions of the Moon: only, the former is a perceptual, hence *subjective*, fact, whereas the latter are *objective* physical facts. There is then nothing wrong with admitting phenomena alongside nonphenomenal (or transphenomenal) facts. The opposition is not between appearance and reality but between subjective facts or accounts and objective facts or accounts.

From the fact that perception gives us only appearances, and the (false) hypothesis that perception is the only source of knowledge, some philosophers have concluded that there *are* only appearances, and others that only appearances can be *known.* The former (e.g. Berkeley) are *ontological phenomenalists,* the latter (e.g. Kant) are *epistemological phenomenalists.* Ontological phenomenalists hold that there is no world independent of the knowing subject: that to be is to perceive or to be perceived. Epistemological phenomenalists hold that, although there may be an autonomous world, i.e. a reality independent of the knowing subject, it cannot be known: at most we may construct fictitious worlds. Clearly, ontological phenomenalism entails epistemological phenomenalism.

A rigorous phenomenalist cannot go beyond appearances and must limit himself to describing or forecasting them: any attempt to understand them would lead him far beyond his own experiential horizon, into the wide world. Thus he will utter subject-centered sentences such as *Phenomenon x* *appears to subject y under circumstance z*. To the realist this is just a truncation of the full sentence *Phenomenon x, appearing to subject y under circumstance z, is caused by (or is indicative of) noumenon w*. And, in addition to such mixed sentences involving objective as well as subjective items, the realist will construct strictly objective sentences such as *Fact x occurs under circumstance z*. Indeed, he will attempt to translate all subjective and mixed sentences into strictly objective ones. This does not entail ignoring subjectivity but putting it in a wider context as well as trying to explain it.

Needless to say, scientists and technologists, regardless of their explicit profession of philosophical faith, behave like realists not phenomenalists. Thus if somebody complains that he feels *X*, his physician will probably conjecture that his patient has (objectively) ailment *Y*, which manifests itself as symptom (phenomenon) *X*. And the biologist will try to explain this cause-symptom relation in physiological terms. Nor is this realistic attitude confined to science and technology: it also permeates the arts. Thus Leonardo and Michelangelo studied anatomy in order to understand what they saw and thus be able to reproduce it more faithfully. Those who do not know "which nerve or muscle is the cause of each movement" are bound to "draw their nude figures looking like wood, devoid of grace" (Leonardo, 1492 or 1515, No. 488).

Phenomenalism, in either version, has been an obstacle to the inquiry into the real world, for it discourages the hypothesizing of objective facts behind phenomena, and it encourages instead the formation of superficial (phenomenological, behavioristic, black-box) hypotheses, and even the survival of an anthropomorphic world view. (Phenomenalism is the last ditch stand of anthropomorphism.) Nevertheless, phenomenalism has been embraced by a number of influential thinkers after Berkeley and Kant, such as Mill, Avenarius, Mach, Whitehead and at one time Russell, Carnap, Ayer, and Goodman. Besides, it has made a decisive contribution to the methodology of behaviorism (Watson, 1925), to the operationalist philosophy of physics (Bridgman, 1927), and to the so-called Copenhagen interpretation of quantum mechanics.

Phenomenalism, in either its ontological or its epistemological version, is false. First, as noted long ago by Plato (*Theaetetus* 158) against Protagoras, our ability to distinguish dreams and illusions from realities refutes the *esse est percipi* doctrine. Second, the very notion of a phenomenon or appearance is unintelligible apart from its dual, that of objective fact. (Thus it makes sense to estimate real sizes and relate them to apparent sizes only because we can distinguish them.) Third, every indirect observation, particularly if quantitative, employs hypotheses (such as law statements) that go beyond phenomena. Fourth, whereas some facts are observer-invariant, i.e. the same for all knowing subjects, others are not—and it is a task of scientific research to find out which are what. Fifth, the present can be explained only by assuming—as cosmology, geology, evolutionary biology and other sciences do—that there were real things before animals capable of perceiving them evolved. In short, the collection of all possible phenomena is only a (smallish) subset of the collection of all possible facts.

Yet, however insignificant appearances may be from an ontological point of view, they occupy a central position in epistemology. In fact, there is no way of gaining some deep knowledge about reality except by combining phenomena with hypotheses and processing both by reasoning. Not that, as James held (1890, II, p. 7), "Sensations are the stable rock, the terminus a quo and the terminus ad quem of thought"—for perception is fallible and has a very restricted scope. Phenomena are central to knowledge for different and various reasons. First because they *pose problems*—e.g. "Why do we perceive X?", "Why cannot we perceive X?", "Is X real or illusory?", and "Why does X appear to us now as Y, now as Z?" Second, because phenomena, when under control, *test* factual hypotheses—as in "If X is the case, then we must be able to observe Y. Now, we failed to observe Y. Therefore X cannot be the case." As James (1890, II, p. 301) put it, "What science means by 'verification' is no more than this, that no object of conception shall be believed which sooner or later has not some permanent and vivid object of sensation for its *term*. [...] Sensible objects are thus either our realities or the tests of our realities. Conceived objects must show sensible effects or else be disbelieved. [...] Strange mutual dependence this, in which the appearance needs the reality in order to exist, but the reality needs the appearance in order to be known!"

Since phenomena constitute only a very special kind of fact, real existence and the totality of real existents (i.e. reality) cannot be defined in terms of phenomena. In particular it is incorrect to define a real thing as a permanent possibility of being perceived (Mill, 1843, Bk. III, Ch. 24, Section 1). On the contrary, we must define appearance, or the totality of phenomena, as the collection of all (actual or possible) perceptual processes in all animals past, present and future. (We may also specify and speak of human appearance, blue jay appearance, sardine appearance, etc.) But, since we test existence hypotheses with the help of phenomena, the latter do provide a criterion of real existence. We propose the following *criterion* (not definition) of objective existence:

X exists only if the following conditions are met jointly:

(i) there are processes in X that produce, directly, or indirectly (i.e. via some other item), some perceptible effect Y;
(ii) this effect is observed by any competent observer in similar circumstances;
(iii) the link between X and Y can be rationally justified (preferably in terms of law statements).

Clause (i) includes the most commonly accepted reality criterion, namely "Being is acting (or having efficacy)". Since the universe as a whole cannot act upon anything, yet is real, this criterion, unlike ours, leaves out the universe. Clause (ii) is the condition of publicity or sociality of objective knowledge: an existence hypothesis proposed by a single individual, whether crackpot or genius, will not be accepted unless independently confirmed. And clause (iii) is the rationality condition: a dogmatic existence statement is unacceptable, for we must understand, at least in outline, the link between the phenomenon and the purported objective fact.

The above existence criterion is peculiar to *critical* (as opposed to naive) *realism*. This class of epistemological doctrines is contrasted in Table 4.1 to alternative views.

TABLE 4.1
Views on the relation of existence to perception.

Thesis	*Antithesis*
1. All perceptibles are real. (*Naive realism*)	1′. Some perceptibles are not (objectively) real.
2. All existents are perceptible. (*Naive phenomenalism*)	2′. Some existents are imperceptible.
3. All and only perceptibles are real. (*Phenomenalism*)	3′. Some existents are imperceptible or some perceptibles are not (objectively) real.
4. No existents are perceptible. (*Buddhism*)	4′. Some existents are perceptible.
5. All imperceptibles are real. (*Platonism*)	5′. Some (objects) are neither real nor perceptible.

4. CONCLUDING REMARKS

Only philosophers have questioned the principle that perception is necessary for knowing reality, and only philosophers have claimed that it is sufficient. Everyone else agrees that perception is necessary though insufficient: that it does yield knowledge (perceptual knowledge), though low grade and fallible. We all know that one and the same external object may appear small to an adult and big to a child, warm to an observer coming from cold outdoors and cold to another staying indoors. We all realize that we are not good at estimating directly vertical distances, very small or very large weights, and mental or social states. And many of us know also that by far the most numerous properties calculated or measured in factual science are just imperceptible. But we also know that any such properties, to be known, must be somehow related to sensible ones—via hypotheses, instruments, or both. True, perception is often deceptive: Figure 4.6. However, we can often discover and correct such perceptual errors, e.g. by checking with other senses, or other people, or by scientific analysis.

What holds for perception holds also for action and, indeed, for all types of experience: experience is no *solid* ground of knowledge but it is (metaphorically speaking) one of the two inputs to our cognitive apparatus—the other being reason. (Strictly speaking all experience is either past or future, hence hardly a solid basis for anything.) Strictly experiential judgments, of the forms 'I feel *X*', 'I do *Y*', 'I feel *X* when I do *Y*', 'I do *Y* when I feel *X*', and the like, are not objective because they report on a changing subject-object relation rather than on a subject-free object. Objective statements do not include reference to the subject. Such objectivity can be attained in either of two ways: really or illusorily. The

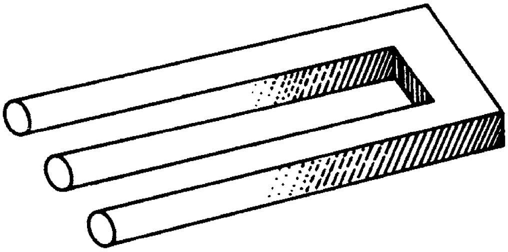

Fig. 4.6. The Devil's Trident: physically impossible. An illusion produced by trickery.

former by thinking up hypotheses about facts in themselves, i.e. independent of the way they are perceived, and putting such hypotheses to the test. This is the way of science and technology. The illusory way of attaining objectivity is the linguistic trick of substituting the impersonal 'It feels *X*', '*Y* is done', etc., for the personal 'I feel *X*', 'I do *Y*', etc.

Science and technology strive for objectivity, i.e. for knowledge of things in themselves. In other words science and technology discover or make facts but do not invent or construct them: what they do invent or construct is concepts, hypotheses, theories, methods, plans, and artifacts. This is not the view of subjectivistic philosophies, whether extreme like Berkeley's or moderate like Kant's. According to these philosophies there are no objective facts or, if there are any, they are unknowable: all facts would be man-made.

There are two kinds of subjectivism (or radical constructivism): individualist and collectivist. According to the former the individual knowing subject constructs the (his) world; according to collectivist constructivism, the world is an outcome of a collective activity. Individualist subjectivism is well known from classical philosophy, but it has hardly any followers among contemporary philosophers. Paradoxically it has some among theoretical physicists, particularly those who, following Bohr (1935), are wedded to the operationalist interpretation of quantum mechanics and state that nothing is an event ("phenomenon") unless it is observed by someone. Thus we are told that "We know now that the moon is demonstrably not there when nobody looks" (Mermin, 1981). (For a criticism of the subjectivistic misreading of quantum mechanics see Bunge (1973) and Vol. 6.) The following paradox demolishes this kind of subjectivism. If a subjectivist claims that nothing exists unless it is observed, then he must own that his own brain cells do not exist as long as their activity is not individually recorded. But this involves inserting an electrode in each of them, which, if technically feasible, would kill him. So, if the subjectivist wants to make sure that he is alive, he must allow a neuroscientist to kill him. It is better to give up subjectivism and stay alive.

Collectivist subjectivism is newer and less well known although it is rapidly gaining in influence. It was first formulated by Fleck (1935), adopted in a less extreme form by Kuhn (1962), and literally by a number of anthropologists and sociologists of science (e.g. Berger and Luckmann, 1966). Thus Latour and Woolgar (1979) claim to describe how Nobel laureate Roger Guillemin "constructed rather than discovered the fact of the thyrotropin-releasing factor". (Moreover he would have discovered such fact not as an outcome of observation, experimentation and hypothesis, but as a result of monitoring a number of "inscription devices" leading ultimately to the final inscription process called 'writing a paper', for which credit can be obtained. They do not explain why the whole process could not have been entrusted to a computer.) The only advantage of this type of constructivism is that it is self-destructive.

Empiricism held that perception is our point of departure, everything else being built upon it. (According to objectivist empiricism, such as Locke's, what we add is conception. On the other hand radical empiricism, such as Mach's, and the later James', claims that that world itself is made up of sensations.) Psychology has shown that there is no perceptual

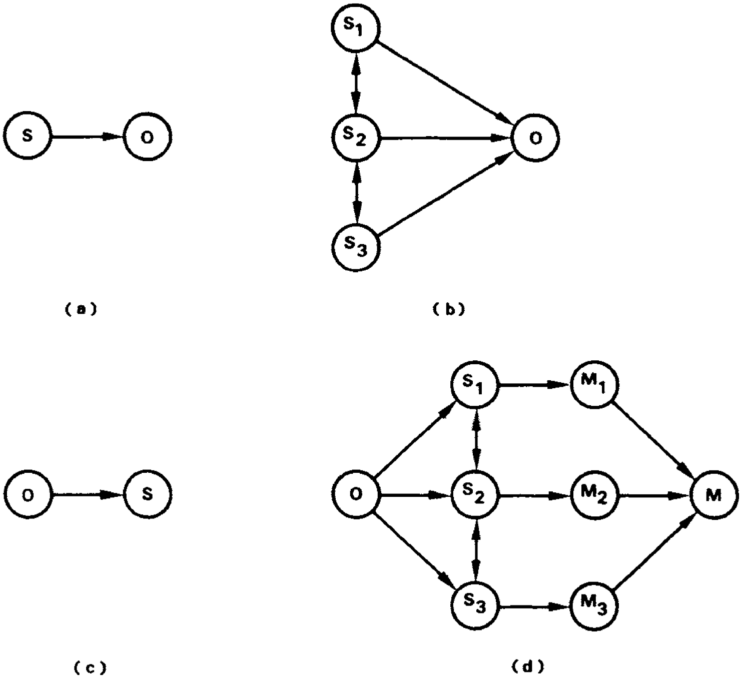

Fig. 4.7. Four views of the subject-object relationship. (*a*) *Individualist subjectivism*: the subject constructs the object, which is either a complex of perceptions (phenomenalism) or a theory (rationalism). (*b*) *Collectivist subjectivism*: the object is constructed by a community of subjects. (*c*) *Individualist realism*: the subject copies or mirrors the object. (*d*) *Social critical realism*: inquirers interacting in a community construct alternative models M_1, M_2, etc. of the object, which are tested until a model M is adopted by most of the members of the community.

"given" to be formulated as a set of indubitable basic sentences. We produce our own perceptions which are colored by our preconceptions, expectations, and social circumstances. All knowledge, whether perceptual or conceptual, is constructed—though not always deliberately.

What we are given is our external world and our genome. We do not have the burden of constructing the whole of reality: we are born into a self-existing world, which we manage to enrich in some respects and to mess up in others. And we are born with certain cognitive abilities that the natural and social environment can enhance or dim—in short, educate. Our perceptual limitations drive us not to constructing reality but to conceptualizing it. And the incompleteness and uncertainty of both individual perception and individual conception advise us to supplement them with, and check them against, those of similar inquirers. The result is that socially related knowing and acting subjects build fallible perceptual and conceptual representations of reality. This is the gist of our epistemology, which is a variety of realism, namely *biological* (as opposed to mentalistic), *social* (as opposed to individualistic), and *critical* (as opposed to naive and dogmatic). See Figure 4.7.

CHAPTER 5

CONCEIVING

We now come to ideas proper, in particular concepts and judgments. Other types of ideas, such as reasonings, problems, and rules, will be treated in subsequent chapters. Although some ideas originate in perception they all overreach it. Sit quietly in a sound-proof room, close your eyes, and think of any intellectual problem. You will be thinking up concepts, most likely not isolated concepts but entire systems of them.

We shall start by examining elementary ideas, i.e. concepts, such as those of book and equality. There are two different concepts of a concept: the psychological and the philosophical one. In psychology a concept is a mental (or brain) process; in philosophy it is a unit construct, or the smallest component of a proposition. In either case concepts are the building blocks of all other ideas. We relate the two concepts when we say that we are thinking of a given concept. Thought is a concrete process, hence one that takes time; on the other hand its object is abstract, in the sense that we detach it from such process and feign that it exists by itself as a timeless object. In this chapter we shall deal with the two notions of a concept, as well as with judgments and their philosophical counterpart, namely propositions.

1. CONCEPT

1.1. *From Percept to Concept*

When seeing or imagining a particular animal we say that we form a *percept* of it—or, more simply, that we *perceive* it. Such a percept, to have any cognitive value at all, must be in some respects analogous to the object perceived or imagined. On the other hand when thinking of humans in general—e.g. that they can conceive anything—we form *concepts* of them, e.g. those of *Homo sapiens, Homo faber, zoon politikon*, etc. Although a concept of this kind derives partly from our perceptions and memories of individual human beings, it is not identical with them. To begin with it is general, and so can bear no resemblance to any individual. A fortiori the so-called abstract concepts, such as those of transitivity, entropy, species, mind, or justice, are not similar to their referents even when they have them.

In other words, the perceptual representation of a thing is a (partial) function of its (apparent) traits into neural events, that preserves some of the relations among such traits (Ch. 4, Section 3.1). On the other hand a concept, or conceptual representation, of the same thing is no such map: it bears no resemblance to its referents, if any. Think of a theory of the electromagnetic field or of the competitive economy, each compressed into a system of equations. This does not mean that, unlike percepts, concepts are in an immaterial mind, let alone an impersonal Mind, rather than in some concrete brain. Concepts are brain processes (or collections of such) but they do not involve any neurosensors even though some of them do originate in perception.

In the above we have tacitly distinguished two kinds of concept: those which originate in perception and those which do not. We may call them *empirical* and *transempirical* (or transcendental) respectively. Idealists deny the existence of the former or render it dependent upon that of the latter. On the other hand empiricists and vulgar materialists (nominalists) deny the existence of transempirical concepts, and hold consequently that the words designating them are just meaningless sounds. Thus whenever Hume (1739) set out to evaluate an idea he asked for its psychological pedigree: *From what (sense) impression cou'd this idea be deriv'd*? Since he could not find the sensory roots of the metaphysical ideas of substance, cause, and self, he dismissed them. Likewise Kant (1787) professed to reject all the concepts of pure reason, particularly if they purported to refer to things in themselves: he too wished to stick to phenomena although he never succeeded. Needless to say, both Hume's and Kant's criticism of transempirical (in particular metaphysical) concepts holds only provided one accepts the empiricist and anthropocentric dogma that only that exists which can make some sense impression on us. (Recall Ch. 4, Section 3.2.)

If Kant and Hume had known the mathematics and physics of their time, they would have rejected them with the same vehemence with which they rejected metaphysics, for those sciences contained key transempirical concepts such as those of function, continuity, and infinity, speed of light, action at a distance, and mass. And they would have disapproved even more strongly of contemporary science, which involves a far more abstract mathematics, as well as factual concepts far removed from experience, such as those of field, electron, and gene. In particular, as Einstein noted, the concepts of theoretical physics are independent of sense experience and are not abstracted from it. "The relation [between concept and percept] is not analogous to that of soup and beef but rather of wardrobe number of overcoat" (1936, p. 353). Consequently "There is no inductive method which could lead to the fundamental concepts of physics" (*op. cit.*, p. 365).

To be sure the concepts of the empirical kind "derive" from percepts. However, they are not mere distillates or summaries of experience. The coining or learning of a new concept of either kind is a creative process: it consists in the emergence of something new that was not in perception, let alone in the external world. (From a neurophysiological point of view it consists in the emergence of a new plastic neuronal system: recall Ch. 1, Section 1.2. Such a process occurs in one of the higher brain centers. This explains why any empirical concept can be aroused by any one of the senses.) We may think of such a process as a map composition, or map of maps: from stimulus objects to percepts and from these to empirical concepts. See Figure 5.1.

The transempirical concepts do not originate in perception, i.e. they cannot be learned from experience but must be acquired by reflection. However, they are not necessarily isolated from all empirical concepts. For one thing some transempirical concepts may be suggested by empirical ones. Thus the empirical ideas of five fingers, five shells, and five children may have suggested forming the transempirical concept of number five. Conversely, some transempirical concepts may suggest empirical concepts and these in turn may guide some experiences. For example, thinking of low temperatures may suggest the idea or the image of a cold drink, which may in turn elicit the idea of paying a visit to the fridge.

In sum, although we emphasize the differences between percept and concept, and between empirical and transempirical concepts, we also assert that the items of these three kinds are not isolated but compose three-tiered *dynamical cognitive networks*. Each of them is related to some others, and each of them can modify some others. This view subsumes both empiricism and idealism, for it admits the creativity of both experience and the

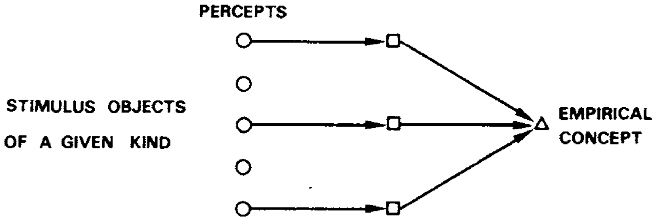

Fig. 5.1. The formation of empirical concepts as map composition.

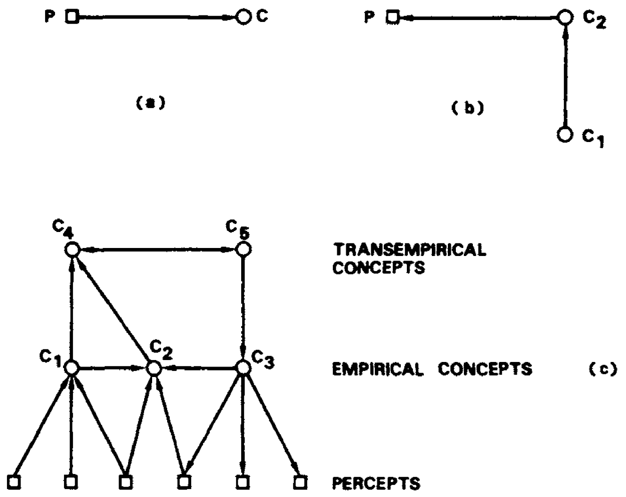

Fig. 5.2. Three views on the relations among percepts and concepts. (*a*) *Empiricism*: Every concept originates in a percept. (*b*) *Idealism*: Every concept originates other concepts, which in turn make some percepts possible. (*c*) *Realism*: Whereas some concepts originate in percepts, others do not; besides, some concepts guide perception and all concepts generate further concepts.

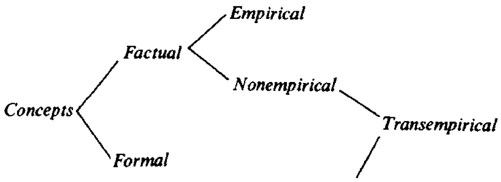
mind—or rather the brain. (See Figure 5.2.) But it transcends the borders of both classical epistemologies in that it suggests looking for the neuronal systems that do the perceiving, the empirical conceiving, and the transempirical conceiving as well as for the mutual actions among such systems. (Note that we are presupposing that perceiving and conceiving are activities of multineuron systems. The idea that there is one neuron for every concept lacks experimental support and is inconsistent with the existence of about 10^{11} neurons in the human brain. Indeed even a supergenius capable of learning one concept every minute would have accumulated, after a long lifetime, only about 50 million concepts, a tiny fraction of the total number of plastic neurons in the human brain: the vast majority would be idle.)

Among the transempirical concepts we distinguish the formal ones, i.e. those occurring in logic, mathematics, and semantics. These concepts are called 'formal' because they do not refer to any facts, whether objective or subjective (experiential). Thus the logical concept of conjunction concerns predicates and propositions, the mathematical concept of limit concerns functions and sequences, and the semantical concept of reference concerns predicates and propositions. That such concepts have no factual reference can only be proved with the help of some theory of reference. (Cf. Vol. 1, Ch. 3.) That, in spite of such lack of factual reference, they can be "applied" in factual science and technology, is another matter to be discussed in Vol. 6.

The admission of formal concepts was a major sacrifice for contemporary empiricism (or logical positivism): it had to be made in order to use logic to analyze and organize empirical knowledge. On the other hand the materialist suffers no setback in admitting formal concepts: all he needs is the hypothesis that all concepts, even the formal ones, are brain processes or collections of such (Bunge, 1981a).

According to logical positivism all facts are experiential, so that all concepts with a factual reference must have an empirical content or meaning, i.e. must be empirical concepts. Hence according to that philosophy the factual/formal dichotomy coincides with the empirical/formal one. This classing is wrong because it is not exhaustive. Indeed there are nonexperiential facts, such as atomic collisions and species extinctions, and we have formed the corresponding transempirical concepts. In other words, whereas some factual concepts are empirical (e.g. "hot") others are transempirical (e.g. "temperature"). This is a firm result of a semantical analysis of scientific concepts (Bunge, 1973, 1974a, 1974b). The concept classification that accounts for the (conceptual) existence of nonempirical factual concepts is this:



Are there any laws of the development of concepts, or rather of our conceptual abilities? We know next to nothing about the conceptual development of children before the first year of age, and this mainly due to their very poor motor and communication abilities. However, neuroanatomical studies show that the cortex of the infant brain is poorly organized and therefore unlikely to perform any conceptual feats: it has small neurons, incompletely myelinated axons, a small dendritic arborization, and few synaptic connections. Older children have been investigated by Piaget and his school for over half a century. These studies have found that there are indeed definite stages in development that cannot be skipped. In particular they have found that the young child has hardly any general concepts: he or she acquires them in the course of development—the pace of which is presumably accelerated by formal education. Once the child has acquired some general concepts—such as that of causation—and some general propositions—such as the principle of conservation of matter—he can use them to construct further concepts as well as to face experience in novel ways.

As for conceptual evolution, we know even less. However, it is likely that all hominids, and perhaps many other higher vertebrates as well, have formed certain general concepts, such as those of existence, presence, place, time, notion, lightness, hotness, hardness, nearness, usefulness, and friendship. A methodical study *à la* Piaget of the conceptual abilities of apes, dolphins, ravens and other animals usually rated as intelligent, is overdue. Also, it would be interesting to investigate the tacit knowledge that must have gone into the fashioning of artifacts by primitive and ancient man. We know little about this in part because of the epistemological prejudice that every concept is preceded by some percept or some action. We know much more about the history of ideas. One thing we have learned from it is that, at least from the beginning of civilization, it is just not true that every complex idea has been preceded by simpler ideas. Whereas much progress consists in complication, some of it involves simplification. Besides, some very basic ideas, such as those of set and concatenation, were introduced long after far more complicated ideas—e.g. those of the infinitesimal calculus—had been invented. In short, there are laws of conceptual development but not of conceptual evolution.

1.2. *Concept Formation*

Let us now examine a handful of very basic conceptual operations. They are so basic that we usually take them for granted and therefore do not pause to analyze them. After all, it behoves philosophers to puzzle what others take for obvious.

The most basic relation among any two items, whether factual or conceptual, is that of difference. The perception or conception of difference is called *discrimination* (or *analysis*). Its dual, the failure to differentiate, is of course confusion. Our perceptual apparatus has a very restricted discriminatory (or analytic or resolving) power, but we can enhance it with the help of observation instruments. Likewise we can sharpen conceptual discrimination or analysis with the help of logic and mathematics.

We must guard against the temptation of detaching whatever is distinguishable. For one thing, properties and changes thereof (i.e. events) are not detachable from the concrete things that possess the properties or undergo the changes. (See Vol. 3, Ch. 2.) For another, every thing is a system or a component of some system, and every system but the entire world interacts with some other system. (See Vol. 4, Ch. 6.) The components of a system, though distinct and therefore distinguishable (at least in principle), are not separable. (Consequently it is impossible to specify the state of one of them without reference to the state of the others. I.e. the state space of the whole does not equal the union of the state spaces of the components.)

All of the mistakes alluded to above have been erected into philosophical doctrines. Thus (philosophical) *atomism* conceives the world as a heap (not a system) of detached or separate units (atoms): it has no use for systems possessing (emergent) properties not possessed by their components. Its dual, namely *holism*, prefers confusion: it proclaims that whatever cannot be detached is one. (See Vol. 4, Ch. 1.) Holists abhor analysis believing that it destroys wholeness, while actually it is the only way to understand wholes. Finally *dialectics* declares differents to be opposites, while at the same time proclaiming the unity of opposites. Since it does not analyze the concepts of opposition and of unity, dialectics is not easy to understand, hence to evaluate. (See Bunge (1981a) for a criticism.)

Discriminating between two objects is a modest cognitive achievement—even though, as in astronomy, it may call for an enormous cognitive investment. The next step is to find out what the distinct objects differ in. And this involves taking cognizance of some of their properties. Such cognitive operation is no mere perception: it is a conceptual operation, for it consists in attributing properties. Indeed, in order to be able to attribute a property to an object we must form some concept of such property. This concept may precede the act of attribution or it may be improvised during it, but in any case it must be formed in order for predication to occur. A concept of a property is called an *attribute* or *predicate*. (There are of course unary, binary, and in general *n*-ary predicates. Thus the predicate *between* is ternary, and so is any function of two variables.)

Idealists need not adopt our distinction between properties and predicates, but realists must, and this for the following reasons. First, a property of a thing cannot be detached from the latter: there are no (substantial) properties without things, and no things without properties

(Vol. 3, Ch. 2). On the other hand a predicate, if attributed (truthfully or falsely) to a concrete thing, is a conceptual representation of a thing's property. Second, attribution is a psychological process, hence one studied by psychologists, whereas all sciences are supposed to study properties objectively possessed by objects. Third, one and the same property can often be conceptualized (represented conceptually) by more than one predicate. Thus on a first level of analysis heaviness is representable as a unary predicate ("body *b* is heavy"); on a second level as a binary predicate ("body *b* in gravitational field *c* is heavy"); on a third level as a ternary predicate ("the heaviness of body *b* in gravitational field *c* equals *d*"), and so on. (In general, predicate formation can be construed as a function from properties to sets of predicates.) Fourth, whereas for every attribute there is another attribute equal to the negation of the first, things have only "positive" properties. A thing either possesses *P* or does not possess *P*, but it cannot "possess" not-*P*: negation is *de dicto* not *de re*. (Barnacles do not think, but this is not to say that they exert the function of not thinking. Negation affects the proposition "Barnacles think", not the property of thinking.) Fifth, what holds for negation holds also for disjunction: there are no disjunctive properties although there are disjunctive predicates. There is no such thing as the property of being alive *or* dead, although the predicate "is alive or dead" is perfectly respectable, and moreover tautological. In short, whereas the set of predicates of a given rank and a given reference class forms a Boolean algebra, the corresponding set of properties does not. (See Vol. 3, Ch. 2.)

There are two different ways of forming the concept of a property, i.e. of construing a predicate: intensionally or extensionally. In the former construal the predicate is a function from individual objects to propositions (Vol. 1, Ch. 1, Section 1.2). For example, "Metabolizes" assigns to organism *b* the proposition "*b* metabolizes", and "Interacts" assigns to the ordered pair of things *a* and *b* the proposition "*a* interacts with *b*". The truth value of such propositions is immaterial for the construction of the predicate. However, once we have found out such truth values we can form the extension of the predicate, i.e. the collection of individuals (or pairs, or *n*-tuples) for which the predicate holds. And then we can ascertain whether a given individual (or *n*-tuple) belongs to the extension of a certain predicate. In other words, the ordinary language expression '*b* is *F*' can be construed either as '*Fb*', where *F* is a function, or as '*b* is a member of the extension of *F*'.

Ordinarily the extensional construal presupposes the intensional one, for we must know what predicate we are talking about (and what property it conceptualizes) before inquiring into its extension. However, both construals are equivalent, and mathematicians use them interchangeably. (For example, the axiom of mathematical induction, occurring in arithmetic, can be formulated in either of the following ways: (i) If a property holds for zero and, when holding for an arbitrary number, it also holds for its successor, then it holds for every natural number: (ii) If a set of natural numbers contains zero, and contains also the successor of every natural number it contains, then it contains all natural numbers.)

Nominalists trust only individuals and mistrust concepts and therefore predicates. To them every property must be understood as the collection of individuals possessing it: they conflate predicates with their extensions. This confusion is open to several objections. The most damaging ones are as follows. First, let P_1 and P_2 be two properties of entities of a certain kind K, e.g. the mass and momentum of bodies. Since all K's possess both P_1 and P_2, according to nominalism P_1 is identical to P_2—which contradicts the hypothesis that P_1 and P_2 are different. Besides incurring contradiction, extensionalists and nominalists are confronted with a practical difficulty: they must know all the values of a given function in order to be able to speak of the function. But in practice this is seldom the case: we are not given complete tables but differential equations, recursion formulas, or some other condition defining the function. Moreover we must know such defining conditions in order to be able to compute (some) values of the function. (In addition we need some special technique, such as series expansion, or iteration, or numerical interpolation.) In short, we cannot sacrifice science and mathematics to philosophical prejudice.

When forming concepts we should avoid the dual sins of reification and ideafication. *Reification* is of course the incorrect conception of properties, relations, or even concepts, as entities having an autonomous existence. Classical examples are the idea that sickness is an entity that the patient carries and may pass on to someone else, and the medieval conception of darkness as an entity (*tenebras*). More recent examples are the existentialist notion of nothingness as a thing, and the structuralist idea that structures precede the corresponding structured things. The dual procedure is *ideafication*, or the conceiving of material things or processes as self-existing ideas. Classical examples are the idealist conception of ideas as detached from thinking brains, and of culture as a system of ideas, values, norms, and behavior patterns. To be sure it is permissible, nay sometimes indispensable, to *feign* that mental processes are detached from brains, in order to be able to focus on certain common features of concepts and disregard everything else, in particular the thinkers' circumstances. This is merely an instance of what may be called *methodological abstraction*. But we should keep in mind (or rather brain) that such conception of concepts in themselves is a fiction.

In studying properties we shall do well to distinguish three kinds of them: (*a*) *individual* or possessed by individuals (e.g. the mass of a molecule, the demand for a certain commodity by a certain individual consumer); (*b*) *aggregate* or possessed by aggregates (e.g. the total mass of a conglomerate of bodies, the total demand for a certain merchandise by a society); (*c*) *emergent*, or possessed by a system but not by its components (e.g. the stability of a molecule, the type of an economy). Failure to draw these distinctions results in absurds such as "the average molecule" or "the average consumer" (instead of "the average of property P over an aggregate of molecules—or consumers"). Two cautions are in order. The first is that a number of properties that can be treated as aggregative (hence additive) to a first approximation are actually systemic. This is the case with mass and entropy, as well as with aggregate demand and supply in economics. (Consider: if two blue collar families are friends and neighbors, they can pool their resources to buy one car, whereas separately neither of them might afford to.) Second, a number of properties that seem to be possessed by individuals are actually possessed by components of a system and vanish if the system breaks down. (For example, the property of being a faithful spouse vanishes upon divorce. Likewise some of the properties of producers and consumers depend on the type of economy.)

There are essentially three ways of studying properties: (*a*) to study *particular* properties, such as the surface tension of a given liquid or the feeding habits of animals of a given species in a given environment; (*b*) to study the *distribution* of a given property in a population, e.g. the distribution of fertility in an animal population, or of wealth in a human society; (*c*) to study the *relations between two or more properties* of a thing, e.g. the correlation between unemployment and crime. All three are legitimate concerns, so neither should exclude the other, and all three should be carried out both theoretically and empirically.

Perceiving or conceiving commonalities is no less important, for attaining knowledge, than realizing differences. Two items are said to be *equivalent* (or *equal*) in some respect, i.e. with respect to a given property, just in case they share this property. This definition entails that there are as many equivalence relations as there are properties. It also entails that every equivalence relation is reflexive, symmetrical, and transitive. I.e., for any objects a, b and c in the given set: $a \sim a$ (reflexivity), if $a \sim b$ then $b \sim a$ (symmetry), and if $a \sim b$ and $b \sim c$, then $a \sim c$ (transitivity).

If the transitivity condition is relaxed we obtain the weaker relation of *similarity* or *resemblance*. If a is similar to b, and b similar to c, it may or may not be the case that a resembles c. That is, a and b may share some properties which are not those that b and c share: see Figure 5.3. A qualitative measure of similarity is the intersection of the sets of properties of the similar objects. That is, calling $P(a)$ and $P(b)$ the sets of properties of a and b respectively, we stipulate that the similarity $s(a, b)$ between a and b equals $P(a) \cap P(b)$. By counting the number of shared properties we obtain a quantitative measure. Our qualitative measure allows us to introduce two relations of similarity comparison:

$$a \textit{ is more similar to } b \textit{ than to } c =_{df} s(a, b) \supseteq s(a, c),$$

$$a \textit{ is more similar to } b \textit{ than } c \textit{ to } d =_{df} s(a, b) \supseteq s(c, d).$$

If two items are distinct (i.e. really two instead of one), and yet equivalent in some respect, then they can be put into a single class. (Not so if they are merely similar.) Note the expression 'can be put' instead of 'exist'. Differences among factual items are objective: they exist whether or not a given subject knows it. On the other hand grouping is a conceptual operation: classes are concepts, not real (concrete, material) entities. But of course whereas some groupings are arbitrary or artificial others are natural or objective. Thus by putting together all the persons called John we obtain an artificial class, whereas by grouping all the persons sharing some common ancestors we obtain a natural class, i.e. a collection whose members are objectively related. (For the notion of natural class see Vol. 3, Ch. 3.)

The operation of grouping or collecting is a basic animal behavior: all animals gather things of some kind or other, and the higher vertebrates are also capable of collecting ideas, i.e. of grouping images, concepts, propositions, and the like. Material things can be put together spatially or

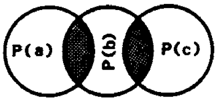


Fig. 5.3. The properties shared by a and b are not the same as those b and c have in common. Hence, although a is similar to b, and b similar to c, a does not resemble c.

temporally; and all objects, regardless of their nature, can be put together in thought. In the former case the outcome is a material thing: a conglomerate or a system; in the second case the outcome is a concept: a set. And in either case the outcome is assumed to be independent of the order in which the items have been gathered: i.e. the result is either an unordered aggregate or an unordered set—or perhaps the matter of ordering has been disregarded on purpose. We are concerned here with collecting items of any nature whatever, whether factual or conceptual, to form conceptual collections, i.e. classes. Whereas some classes are realistic (not arbitrary), no class is real. We shall come back to this subject in relation to biological taxonomy (Vol. 6).

(The operation of collecting or grouping can be defined as follows. Consider three items: 0, a, and b, forming the following binary compounds or concatenates: $00, 0a, a0, 0b, b0, aa, bb, ab$, and ba. Assume that $00 = 0$, $0a = a0 = a$. $0b = b0 = b$, $aa = a$, $bb = b$, and $ab = ba$. In other words, 0 is the null object, and concatenation is idempotent and commutative. We now define the *collecting* or *bracketing* operation $\{\ \}$ by the following assignments:

$$0 \mapsto \{\ \};$$

$$a \mapsto \{a\}, \qquad b \mapsto \{b\};$$

$$ab \mapsto \{a, b\}.$$

From the assumed properties of the concatenation it follows that

$$aa \mapsto \{a\}, \quad bb \mapsto \{b\}, \quad ba \mapsto \{a, b\}.$$

In the above, a and b may be any objects, whether material or conceptual. On the other hand 0, the null object, can only be conceptual: nothingness has no real existence. Finally, we define $\varnothing =_{df} \{\ \}$.)

When collecting real (material) things we must recall that they are changeable, to the point that whereas some of them may have already vanished others may not yet have come into being. (Think of mankind, or the human species.) We must therefore distinguish between a collection that varies in time and a set, or collection regarded *sub specie aeternitatis*. The membership of the former is variable, whereas that of the latter is constant: all the elements in the latter are treated as if they were timeless entities. The difference between the two collecting operations can be elucidated with the help of the notion of time, which is of course a scientific and ontological concept, not one in pure mathematics. In fact call F the attribute of interest and write 'Fxt' to indicate that x has property F at time t. Then the *collection of all F's at time t* will be

$$S_t = \{x \mid Fxt\}.$$

(Instead of augmenting the n-arity of predicates we can also use the operation of bracketing at a given instant or over a given time interval, or $\{\ \}_t$ for short. This operation can be defined by adding t to the individuals $0, a$, and b used to define the timeless bracketing operation $\{\ \}$, and requiring that it obey the following conditions:

$$0t \mapsto \{\ \}_t;$$

$$at \mapsto \{a\}_t, \qquad bt \mapsto \{b\}_t;$$

$$abt \mapsto \{a, b\}_t.$$

The expression '$\{a, b\}_t$' is read 'the set formed by a and b at (or during) t'.)

By taking the union of all the variable collections of F's for all time we get the (timeless) *set* of Fs, or the *extension* of the predicate F. (In physics many predicates are frame dependent, so it may be necessary to add a subscript naming the particular reference frame relative to which the collecting is done.)

Just as we can analyze individual things and individual ideas, so we can analyze collections of either. The most basic mode of analysis of a collection is its *partition* into homogeneous subcollections. For example, a human population can be analyzed into collections of individuals of the same sex, the same age, or the same number of schooling years, etc. The key to such partition is the concept of sameness in some respect, i.e. of equivalence, examined a while ago. One says that an equivalence relation *induces the partition* of a collection into a family of *equivalence classes*, and that all the members of each equivalence class are equivalent (or equal) in the given respect. The operation resulting in the formation of such family is called the *quotient* of the given set S by the given equivalence relation $\sim$ (written '$S/\sim$'). For example, the quotient of the set of integers by the relation of equal parity is the family composed by the set of even numbers and the set of odd numbers. (I.e. $\mathbb{Z} = \{E, \bar{E}\}$, where $E = \{x \in \mathbb{Z} \mid (\exists y)(x = 2y)\}$, and $\bar{E} = \{u \in \mathbb{Z} \mid (\exists v)(u = 2v + 1)\}$.) We shall use this notion when studying the principles of classification (Ch. 9 Section 1.1).

It has been noted that, whereas some people excel at analyzing, others are better at synthesizing: few are at the same time good splitters and good lumpers. Yet both abilities are needed, for whereas some lines of inquiry start by distinguishing or resolving, others begin by fusing or lumping, and all research projects include these two moments. Indeed, analysis does not go far without interrelation, and in turn interrelation may result in the recognition of wholes. So, splitters as well as lumpers discharge a useful function in any inquiring community—provided each of them does not enshrine his own ability as a philosophy (atomism and holism respectively) and proclaims the superiority of it.

So far we have encountered concepts of three basic types: individuals, collections of such, and functions. In the present stage of the evolution of ideas every concept is either an individual concept (e.g. "Earth"), a collection (e.g. that of all solar planets), a function (e.g. "not"), or some construction out of concepts of such basic types. For example, an ordered n-tuple may (but need not) be construed as a certain set of sets. (E.g. $\langle a, b\rangle = \{\{a\}, \{a, b\}\}$.) A vector may be analyzed as an n-tuple of real numbers and also as a unit component of a vector space.

The general concept of an n-tuple and the more special one of a vector are formal concepts. However, they can be applied to real life situations. Consider a set of commodities (goods or services). Call q_i the quantity of the ith commodity, measured in appropriate units, and p_i the corresponding unit price in dollars. Then the value of the amount q_i of commodity i is by definition the product $p_i q_i$. A collection or bundle of commodities q_1, $q_2, \ldots, q_n$ can be conceptualized as an ordered n-tuple. Prices are parallel. The price structure or value of a bundle of commodities is then defined as the product $v(q) = pq$ of the vectors $p = \langle p_1, p_2, \ldots, p_n\rangle$ and $q = \langle q_1, q_2, \ldots, q_n\rangle$. This notion allows one to compare the values of different commodity bundles. In fact we stipulate that $v(q) \geq v(q')$ if and only if $pq \geq p'q'$. In this manner we can conceptualize a whole bundle of commodities as a single concept, and reduce the comparison of two bundles of commodities to comparing two numbers. Moreover all of the concepts involved in the above process are exact.

The general concept of an n-tuple is abstract, that of an n-tuple of real numbers (or vector) is less so, and that of a commodity bundle is not at all abstract. This kind of abstraction may be called *semantical* because it is the dual of semantic interpretation. In fact we get the notion of a vector by interpreting the components of an n-tuple as real numbers, and the notion of a commodity bundle by interpreting in turn those real numbers as quantities of commodities. In other words the factual concept (of commodity bundle) results from the factual interpretation of a mathematical interpretation of an abstract concept. (For the composition of the two interpretation maps see Vol. 2, Ch. 6.) Semantical abstraction is, in short, the dual or inverse of interpretation.

Another concept of abstraction may be called *methodological*, as it consists in deliberately disregarding certain properties. It is identical with that of equivalence. Indeed, if in comparing two objects we abstract from (disregard) all their properties except those they share, we build an equivalence relation allowing us to partition the given set into equivalence classes. (Recall what was said about equivalence a while ago.) An instance of this notion of abstraction is the formation of the concept of relation apart from the relata. Thus take all the possible statements of the form "x lies to the right of y", and abstract from the relata, i.e. consider the relation of lying to the right: this concept is methodologically abstract. Clearly, every time we generalize and every time we build a model of a real thing we disregard certain properties and thus perform a methodological abstraction.

A third concept of abstraction is *epistemological*, for it consists in remoteness from ordinary experience, in particular perception. Epistemological abstraction consists in replacing phenomenal properties with nonphenomenal ones, hence in replacing empirical concepts with transempirical ones. (Recall Section 1.1.) For example, the empirical (subjective) statement "I feel colder now" suggests either of the following transempirical (objective) statements: "The air temperature has dropped" or "There may be something wrong with the subject's health". All mathematical concepts and most of the theoretical concepts in science and technology are epistemologically abstract. Only psychology employs phenomenal concepts, such as that of loudness, alongside transempirical ones, such as sound intensity— and this for the good reason that it wishes to account for subjective experience, not only for objective facts.

The three concepts of abstraction are different but they are logically related. The relation is this: Whatever is either semantically or methodologically abstract is also epistemologically abstract—but the converse is false. All three concepts seem to come in degrees. However, so far only semantical abstraction has been quantitated (Vol. 2, Ch. 6). The quantitation of methodological and epistemological abstraction is an open problem. But at least in a few cases we can order concepts according to epistemological or methodological abstraction. For example, the notions of electromagnetic potential, electromagnetic field intensity, and ponderomotive force, form a ladder of descending epistemological abstraction.

And the concepts of vertebrate, animal, and organism form a ladder of ascending methodological abstraction.

Finally, are there inconceivables, i.e. facts that cannot be conceived of, or concepts that cannot be formed? If there are any we cannot say a priori which they are for, if we did, we would have some conception of them. What we may freely grant is that some facts will forever remain unknown to us, and some conceptual processes are beyond our capacity. But we cannot always specify which ones. Still, we should remember that a number of inconceivables have turned out to be conceivable. Two classical examples are the irrational numbers and change. The former were inconceivable within the Pythagorean doctrine, which held that every number was either an integer or a ratio of integers. As for change, from Parmenides to Bergson a long string of philosophers proclaimed that, although it may be intuited, it cannot be conceived. Yet modern mathematics enlarged the narrow Pythagorean context and moreover proved that there are infinitely many more irrationals than rationals. And modern science places equations of change (motion, field propagation, chemical or nuclear reaction, organic growth, social mobility, etc.) at its very center. So, it is more prudent to talk about *unconceived for the time being* than about inconceivables. And in any case it is more fruitful to try and form new concepts than to speculate about our unknown conceptual limitations.

2. PROPOSITION

2.1. *From Thought to Proposition*

We are now ready to examine complex conceptual operations and, in the first place, thoughts such as thinking that psychology is interesting, that psychology must be allied to sociology, and that all conceptual operations are neurophysiological processes. We have just exemplified three modes of judgment: attribution, association, and generalization. We shall study these basic modes of judgment after the following preliminaries.

Thinking is a brain process the psychological units or modules of which are concepts. Each concept is identical with the specific activity or function of some psychon or plastic neuronal system. (Ch. 2, Section 2.2.) Forming a judgment is thinking of several concepts in quick succession or simultaneously. Therefore judging is identical with the sequential activation of a number of psychons—or perhaps with the simultaneous activation of them. And believing is even more complex, for it is identical to

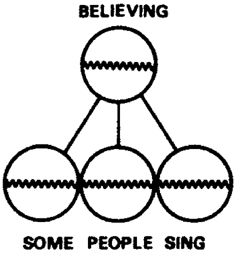

Fig. 5.4. Schematic representation of the sequential activation of the psychons constituting the judgment that some people sing. The evaluating psychon on top does the believing (or disbelieving).

giving assent to such thoughts. Hence presumably believing involves not only conceptual psychons but evaluating ones as well. See Figure 5.4.

Every judgment is a sequence of concepts but the converse is false. Thus the sequence of concepts expressed by the phrase 'She got' is only part of a judgment. We know how to characterize a complete sentence and a well formed proposition, but we still do not know what characterizes a complete judgment. That is, we still have to learn what are the neurophysiological characteristics of a complete judgment as distinct from an arbitrary sequence (or association) of active psychons. This will force us to work most of the time with the conceptual and linguistic manifestations of judgments, i.e. with propositions and sentences respectively.

We may as well start by emphasizing the difference between judgments and propositions. Whereas the former are brain processes, the latter are collections of such and, more particularly, equivalence classes of judgments (Ch. 2, Section 2.2). Consider an external fact such as the song of a bird in a neighborhood. A number of observers may think of this fact, and some of them may agree that it is too early for this time of the year. Most likely the brain processes the various observers go through when thinking this are, though equivalent in some respect, different in other respects. Yet they must be the same in one respect, namely that all of them consist in thinking that the perceived song is too early for this time of the year. And this is precisely the proposition designated by the English sentence 'That song is too early for this time of the year', the Spanish sentence 'Ese canto es muy temprano dada la estación del año', and hundreds of others. Moreover each of these sentences can be uttered in a variety of ways, and likewise each of those judgments can be believed with different intensities. Figure 5.5 summarizes these distinctions, which unfortunately are not always made.

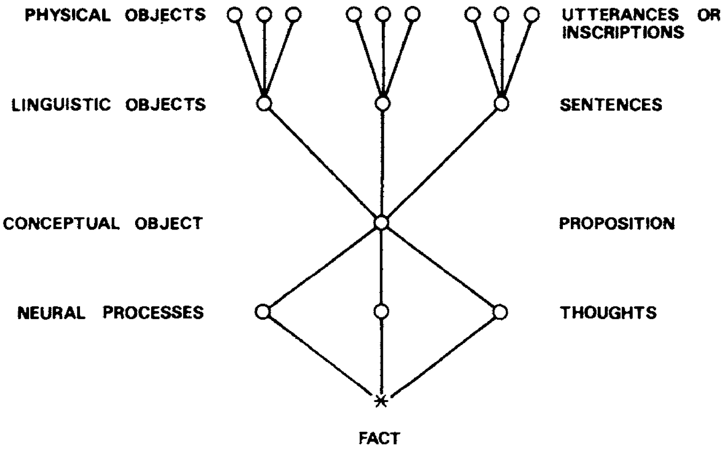

Fig. 5.5. The proposition as an equivalence class of thoughts and the sentence as an equivalence class of utterances or inscriptions.

Some of the categories we have just mentioned are deliberately fused for philosophical reasons. (Fusing is not the same as confusing: the former is conscious equation, the latter is lack of discrimination.) Thus propositions are sometimes called 'facts', perhaps under the influence of idealism. And it is still common to call propositions 'sentences' (and accordingly to speak about the 'sentential calculus') because of the nominalistic prejudice against conceptual objects. Although in most cases such confusions are harmless, in others they are misleading.

(An example of the latter is the problem area of counterfactuals. An entire industry has been built upon the mistaking of counterfactual conditionals for propositions, while actually they are not even sentences. In fact, counterfactuals are ambiguous utterances or inscriptions. Consider the time-worn counterfactual 'If this lump of sugar were placed in water it would dissolve'. This expression may be interpreted in at least two different ways: either as emphasizing that the given lump of sugar is *not* actually immersed in water, or as emphasizing that, when placed in water, it *dissolves*. The reading is a matter of stress or of italics. In the first case we would say 'If this lump of sugar *were* placed in water it would dissolve'. In the second, 'If this lump of sugar were placed in water it would *dissolve*.' Without some information about the context, in particular the speaker's or writer's intention, it is impossible to disambiguate the utterance or the inscription. Because of this ambiguity counterfactual conditionals have no logical status and do not occur in mathematical or scientific theories. They constitute a pseudoproblem. (See Bunge, 1973b, Ch. 1.) No wonder it is being approached by the bizarre metaphysics of possible worlds, which is not a theory about the only world there is (*Treatise*, Vol. 3, Ch. 4).)

Let us now perform a quick study of the operations of attribution, association, and generalization. *Attribution* is the conceptual operation of assigning a property or a relation to objects of some kind, material or conceptual. Thus when perceiving that *b* is moving we may attribute to *b* the property of moving—or, on second thoughts, we may attribute to ourselves the property of moving relative to *b*. And on perceiving *b* crashing against *c* we may attribute to them the relational property of colliding with one another, or even that of attracting each other. (One and the same percept may elicit no judgment, one judgment, two judgments, or even more.)

When attributing phenomenal (observable) properties to perceptible individual things we may not distinguish between perceiving and conceiving, and may even be tempted to espouse phenomenalism. The difference emerges when thinking of properties regardless of their bearers (e.g. "swiftness") or when attributing nonphenomenal properties (e.g. "external"). In either case we obviously go beyond perception and form concepts: in the first case we generalize, in the second we introduce transempirical concepts.

We may conjecture that attributing property *P* to object *b* consists in the (simultaneous or successive) activation of the psychons for *P* and for *b*. Or we may conjecture that we first think that *b* is (possesses the property) *P*, with a single psychon, and then the psychons for *b* and *P* are activated (or formed) at the same time or sequentially. Or we may also conjecture that sometimes we undergo processes of the first type (synthesis) and at other times processes of the second type (analysis). We still do not know which, if any, of the three hypotheses is true, and we won't find out as long as they are not spelled out (if possible mathematically) and tested experimentally. However, some crude conjectures have to be hazarded before they can be rendered more precise and put to the test.

Things are easier at the conceptual and linguistic levels, where it is a question of forming propositions or sentences, i.e. of gluing predicates to subjects. Consider a predicate or attribute *F* representing (conceptualizing) an intrinsic or non-relational property *P* of objects of some kind *K*. *F* can be construed as a function from *K* to the set of all possible propositions involving *F*. And attributing *P* to a member *b* of *K* is forming the proposition *Fb*, i.e. evaluating the function *F* at *b*.

Association, in particular pairing, is the general case of attribution. Associations can be natural, as those established between lightning and thunder, or hunger and food; or they can be conventional, like those between side of the road and sense of circulation, or house and street number. And objects of any kind may be thought (truly or falsely) to be associated: things to things, events to events, things to events, concepts to concepts, concepts to properties, etc. Whatever its nature and origin, thought of association may be conjectured to be a neural process similar to that of attribution, i.e. either the pairing of psychons or their sequential activation. The mathematical notion of a relation, or n-ary predicate, elucidates that of association at the conceptual level. Thus consider a relational property P of objects of kinds K and L, such as the relations of connecting, eating, or cooperating. P can be construed as a binary predicate G with domain the cartesian product of K and L, and codomain the set of all propositions containing G. In this case attributing P to the pair of objects b in K and c in L consists in forming the proposition Gbc, i.e. in evaluating G at $\langle b,c \rangle$.

Finally we come to *generalization*. There are two kinds of generalization: (*a*) from like cases, i.e. from individuals to species; (*b*) from one species to another. The former consists in discovering or conjecturing a pattern from individual cases. The second type of generalization is what learning theorists call *transfer of learning* (or of skills)—e.g. having learned one foreign language facilitates the learning of another, or learning carpentry facilitates the learning of work with metals. We shall limit ourselves to generalization of the first type.

How do we generalize? Empiricists hold that every general proposition, in particular every law-statement, is an inductive generalization, i.e. a drawing together of particular propositions. Thus every general hypothesis would come at the end of an inductive process, never at the beginning of a testing procedure. On the other hand rationalists and intuitionists hold that we can start with generalities straight away, on the strength of a single case or even a priori. They also believe that no tests are necessary. Experimental psychologists have found that in fact we and other higher animals proceed sometimes as empiricists and other times as rationalists. Although some generalizations culminate repeated observations, others are formed on the strength of a single case or even prior to observation. That all generalizations, no matter what their origin, must be repeatedly tested before being assigned a truth value, is another matter altogether: here we are dealing with the epistemological problem of the origin or mechanism of generalization, not with the methodological problem of validation.

Consider a classical or Pavlovian conditioning experiment. An animal is presented a light (or a tone) and a short time afterwards is given food (or an electric shock). After a few times the animal has learned to associate the two stimuli, so that on being subjected to the first (unconditioned) stimulus he makes the appropriate response (salivation, withdrawal, or what have you) before the second stimulus is delivered. The light (or sound) need not be always the same, and the food (or painful stimulus) can vary as well: the animal learns quickly to pair a whole class *S* of stimuli with an entire class *R* of responses. In mathematical terms, the animal has unwittingly built an entire *function* from *S* (actually from *S* cross the set of its internal states) to *R* out of a few values. (This function is "embodied" in a new configuration of neurons: recall Ch. 2, Section 1.1.) Consequently the animal has acquired a potential or propensity for reacting to further stimuli of the same kind with further responses of the same kind. In short, the animal has generalized—perhaps from a single case. This hypothesis explains instant learning, in particular instant generalization (in contrast to inductive or step by step extension). See Figure 5.6. Incidentally, this hypothesis takes the epistemological aspects of the problem of induction away from philosophy into experimental psychology and neuropsychology. The problem has now become that of identifying the neuronal systems and processes that do the generalizing, either prompted by a handful of cases or prior to observation.

We all know the advantage of generalization: it compresses a large (sometimes infinite) number of epistemic items. (And in the case of the transition of "some" to "all" we also gain in precision.) On the other hand by generalizing we may incur falsity. The whole of magical thinking

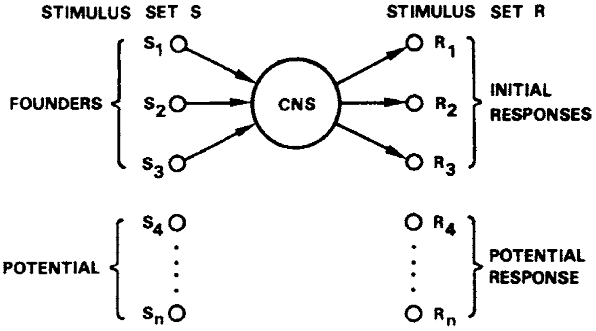

Fig. 5.6. A handful of stimuli are often sufficient to elicit the formation of a new psychon capable of producing new responses of the same kind beyond the initial ones.

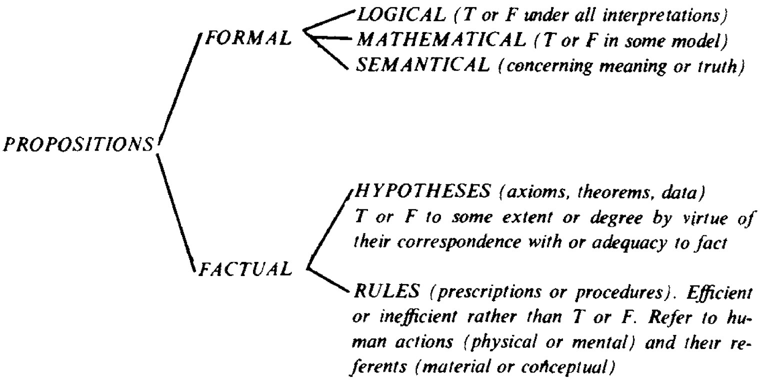
derives from hasty (untested) generalization from coincidences. You came just when I was wishing you to come; I was not injured in the accident because I was carrying my amulet; my wrongdoing was not punished because I had paid my tribute to the deity. When such coincidences occur, our nervous system records them; when they do not, it does not. What is wrong about jumping to general "conclusions" is not the jumping itself—a beautiful instance of creativity—but the refusal to subject the generalization to tests before believing it.

2.2. *A Priori and a Posteriori*

What we take to be the basic distinction among propositions was drawn by Hobbes and elaborated on by Leibniz: it is the one between truths of reason and truths of fact. We generalize to half truths (and falsities) and speak in general of *formal* and *factual propositions*. The former are self-sufficient: they do not describe anything real; the latter describe (truly or falsely) some (possible or actual) fact(s). Thus a theorem in pure mathematics is a formal proposition. On the other hand a theorem in some theoretical factual science, like physics or psychology, though proved with mathematical rigor, rests on factual premises because it concerns real things. Besides, its truth or adequacy to fact must be shown by its consistency with the relevant empirical data.

There are several kinds of formal propositions and likewise several types of factual ones. We class them as follows:



PROPOSITIONS
FORMAL
LOGICAL (T or F under all interpretations)
MATHEMATICAL (T or F in some model)
SEMANTICAL (concerning meaning or truth)
FACTUAL
HYPOTHESES (axioms, theorems, data) T or F to some extent or degree by virtue of their correspondence with or adequacy to fact
RULES (prescriptions or procedures). Efficient or inefficient rather than T or F. Refer to human actions (physical or mental) and their referents (material or conceptual)

The preceding classification is more correct than either of the popular dichotomies analytic/synthetic or a priori/a posteriori. For one thing the concepts of analyticity and aprioriness have not been well defined except in extreme cases. Thus, a tautology is clearly analytic, but what about a theorem in theoretical physics, which has been derived by purely conceptual means? And an empirical datum is clearly a posteriori, but what about a factual hypothesis not built inductively and which happens to anticipate experience correctly? Neither of the two distinctions amounts to a dichotomy, hence neither is a sound principle of classification. When taken together the above classifications produce not only analytic a prioris and synthetic a posterioris but also analytic a posterioris and synthetic a prioris. Our own classification allows us to dispense with all four categories, in particular with the latter.

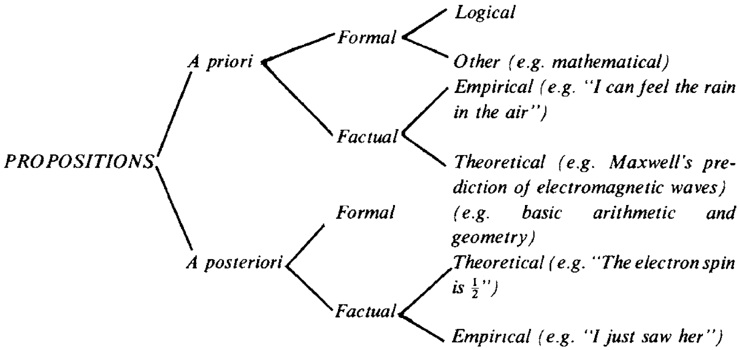
To be sure, it does make sense to use the expressions 'a priori' and 'a posteriori', but with the understanding that they give rise to subjective and shifting distinctions. Subject A conceives a given hypothesis on the strength of his experience; once conceived, the hypothesis functions as an a priori in A's further exploration of the world. Subject B conjectures the very same hypothesis (e.g. by analogy) and uses it to gain new experience (e.g. by employing it in the design of an experiment). Thus the hypothesis is a posteriori for A and a priori for B at a given moment in each subject's cognitive development; and the next moment what was a priori becomes a posteriori and conversely. In short, the definition "x is a priori iff x is prior to experience and independent of it" leads to contradiction. We must relativize it to the knowing subject and his experience, namely thus:

(i) Construct (concept or proposition) x is *a priori* for subject y at time $z =_{df} y$ has formed x by time z, and y has had no experience relevant to x before z (i.e. y knows x without resorting to perception). Otherwise x is *a posteriori* for y at z.

(ii) Construct x is *absolutely a priori* $=_{df}$ x is a priori for any subject at some time. Otherwise x is *absolutely a posteriori.*

These are *epistemological* concepts of aprioriness not to be confused with the *semantic* one of lack of real reference or the *methodological* one of validity regardless of experience. Whereas some mathematical and scientific constructs are epistemologically a priori, only the formal ones are methodologically a priori, i.e. they stand or fall regardless of any empirical operations. Absolutely a priori constructs, such as those of logical consistency, infinity, and topological space, are not to be confused with innate ideas of the kind postulated by Socrates, Freud, or Chomsky. In particular the constructs of logic and mathematics, though seldom originating in experience, cannot be formed without considerable prior experience of some kind. Only our nervous system, possessing certain dispositions built into its very organization, is innate. Thus it is possible that the tendencies to locate external events in space and time, and to search for causal connections, are innate, though perhaps not inborn. However, such dispositions do not constitute knowledge: they are only necessary conditions for learning.

The a priori/a posteriori dichotomy can be elaborated on. In particular, we must admit *factual a prioris*, such as the novel predictions made with the help of some scientific theories. (Think of the "missing links", now found and called *hominids*, or of the forecasts of World War II.) The resulting classification is this:



PROPOSITIONS
A priori
Formal
Logical
Other (e.g. mathematical)
Factual
Empirical (e.g. "I can feel the rain in the air")
Theoretical (e.g. Maxwell's prediction of electromagnetic waves)
A posteriori
Formal
(e.g. basic arithmetic and geometry)
Factual
Theoretical (e.g. "The electron spin is ½")
Empirical (e.g. "I just saw her")

3. EXACTIFICATION

3.1. *From Vagueness to Exactness*

Many, perhaps most of the concepts designated by ordinary language expressions are vague, i.e. imprecise or inexact: think of "small" and "most". Even in mathematics and science newly minted concepts are likely to be somewhat vague, and none becomes completely exact unless incorporated into a theory. Whereas in some cases vagueness is harmless and even expedites thinking—or at least speaking—in others it is a serious stumbling block to thinking and communicating.

Vagueness precludes the use of logic, which deals only with exact predicates. (In particular vague predicates violate the excluded middle principle, which rejects borderline cases by stating that nothing has and fails to have any given attribute.) Take for example the concept "most", the negation of which is "none or some or all". Now, ‘none or some" is tautological, for it amounts to "not some or some". Hence the negation of a most-statement amounts to the disjunction of a tautology and a universal statement. So, no matter what the truth value of the latter may be, the disjunction is logically true—which renders some-statements immune to tests. This shows that the ‘most’ of ordinary language violates logic. But the concept can be exactified, e.g. by construing "Most *A*'s are *B*'s" as "The relative frequency of *A*'s that are also *B*'s exceeds $\frac{1}{2}$". This construal avoids the above paradox.

Vagueness can often be reduced or even eliminated by some conceptual means or other, such as definition, quantitation, or theorization. Thus the expression ‘*B* depends on *A*’ can be rendered exact by construing *A* and *B* as sets, or members of sets, and dependence as a mathematical function from *A* to *B*. (For example, the ontological thesis that the past determines the present may be exactified as "For every thing, and every property of it relative to any given reference frame, there is a function representing that property, with respect to that frame, and such that the current value of the function is a function or a functional of its past values".) The vague concepts of fatness and baldness may be replaced with a certain standard weight value and a certain standard number of hairs respectively. The indefinite "some" may be eliminated either by quantitating or by dividing the original set into homogeneous subsets every member of which possesses the property designated by the predicate in question. And the ever present "etc." may be replaced with either an exhaustive list—which is not always possible—or a mention of the proximate genus. Thus instead of saying ‘spinach, broccoli, string beans, etc.’, we can say ‘green vegetables’, thereby gaining in both precision and breadth. Being a conceptual defect, vagueness can be reduced only by conceptual means: purely linguistic tricks will not help.

Vagueness is imprecision in meaning. Now, meaning can be construed as composed of sense and reference or, in self-explanatory symbols, $\mathcal{M}(c) = \langle \mathcal{S}(c), \mathcal{R}(c) \rangle$ (Vol. 2, Ch. 7). The sense of a construct in a given context equals the set of its logical relatives, i.e. implicants and implicates. And its reference class is of course the set of all the objects referred to by the construct. (Caution: Reference must not be mistaken for extension. A predicate referring to mythical objects refers and yet has an empty extension.) Since the meaning of a concept is composed of its sense and its reference, its vagueness can be of either. We shall therefore speak of intensional and referential vagueness. Moreover an imprecise sense may result in a somewhat indefinite reference class: think of the concepts of thing, organism, thought, and democracy.

The concept of *intensional vagueness* can be analyzed in terms of the full but unknown sense $\mathscr{S}(c)$ of a construct c, and the subset $\mathscr{S}_k(c)$ of known members of its sense, namely thus: $\mathscr{V}_i(c) = \mathscr{S}(c) - \mathscr{S}_k(c)$. But, since only $\mathscr{S}_k(c)$ is well determined, the concept of intensional vagueness is itself vague and therefore of little use. See Figure 5.7. On the other hand the concept of referential vagueness is quite clear-cut. A reliable test for the referential definiteness of a predicate is its performance in dichotomy: if a predicate allows us to unambiguously and exhaustively perform a partition of any set into the subset of all the members with the given property and the complementary subset of all those elements that lack it, then the reference class of the predicate is entirely definite. If, on the other hand, there are borderline cases that might as well be grouped with one category or its complement, then the predicate is referentially vague.

(A precise measure of such vagueness is provided by the fraction of borderline cases. In obvious symbols, $\mathscr{V}_r(c) = n/N$, a formula that works only for finite universes of discourse. It follows that $\mathscr{V}_r(\neg c) = \mathscr{V}_r(c)$, i.e. referential vagueness is shared to the same extent by a concept and its dual. And the *degree of definiteness* of c may be defined as the complement of that number to unity. Warning: These are just the degrees of referential vagueness or definiteness *known* at a given moment to a given knowing subject. Different workers may and, in fact, usually do, come up with different counts of borderline cases—a common occurrence in ordinary life as well as in biological and sociological systematics. So, although the concept of referential vagueness is quite precise, its application varies from

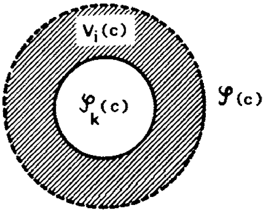


Fig. 5.7. Intensional vagueness: the ill-limited shaded zone.

subject to subject. Finally, the *total vagueness* or *indefiniteness* of a concept c may be defined as $\mathscr{V}(c) = \langle \mathscr{V}_i(c), \mathscr{V}_r(c) \rangle$.)

Intensional vagueness is a necessary but insufficient condition for referential vagueness. I.e., if a concept is referentially vague then it is also intensionally vague but the converse need not be true. In fact intensional vagueness can often be palliated by introducing and using practical *criteria* (decision rules) enabling one to decide whether a given object belongs to the reference class of the concept in question. Thus long before any of the essential properties of gold were known, chemists used *aqua reqia* for identifying golden things. And, although nobody knows what scientific talent is, anybody can spot it by counting numbers of tough solved problems, or even publications.

However, in scientific contexts we cannot be satisfied with referential precision: we also need intensional definiteness. This is best achieved by turning the given context into a member of a mathematical theory. However, mathematization has its limits: (*a*) it is only necessary, not sufficient, as shown by the case of fuzzy set theory, and (*b*) it concerns only the form or structure of a concept, not its factual reference. In any event, regardless of the means whereby a construct is sharpened, we may stipulate that a construct is *exact* if and only if it is not vague—i.e. if both its intensional and its referential vagueness are nil.

To *exactify* a concept, then, is to replace it with another having a precise sense and a precise reference, each of which has a sizable overlap with the sense and the reference, respectively, of the original imprecise concept. A perfect coincidence of sense and reference cannot be expected: every time a concept is exactified something is gained and something else—usually simplicity and intuitiveness—is lost. Think of the contemporary concepts of number, matter, and life, as compared with their predecessors.

Needless to say, exactification is not identical with quantitation: there are numerous qualitative mathematical disciplines, such as logic, abstract algebra, and topology. Nor is exactification restricted to the natural sciences: there is a vigorous exactification movement in the social sciences and the humanities, not excluding philosophy. (See, e.g. Bunge (Ed.), 1973d.)

Concept refinement, or exactification, is one aspect of the progress of knowledge. In fact the latter does not consist in piling up new data and new conjectures, but in a selective process that pivots around the invention and improvement of concepts, propositions, theories, and methods. In this process concept refinement plays an indispensable part: although it does not replace the original invention of an initially imprecise idea, it helps to develop it. This must be insisted on because the role of concept refinement has been exaggerated by some and underrated by others. The overrating has been mainly the work of theorists, which is understandable, for they are professional concept breeders. And the underrating is not surprising either in view of the empiricist tenet that genuine research is concerned only with fact finding. This one-sided view was justified at the beginning of the modern era, as a reaction against the hollow verbosity of decadent scholasticism. Recall that Bacon advertised his own philosophy as "a philosophy of works, not of words", and that the Royal Society of London took from him its motto *Nullius in verba*—"There is nothing in words".

The anti-intellectualist tendency became obsolete no sooner it was born, for modern science and the technology based on it are as conceptual as they are empirical. In fact many problems in science and modern technology are problems of concept formation or refinement, which occur in the building, application, and evaluation of theories. Think of the two centuries of scientific debates over the term 'force', which turned out to designate now the concept of force proper, now that of energy, now that of power. Or, to turn to present day problems, think of the notions of mind, creativity, and intelligence, which still roam wildly in psychology. Or of the concepts of economic value, money, and social class, paragons of inexactness in social science. The vagueness of these notions hampers theoretical development and empirical research: it only encourages confusion and barren argumentation. (See an unabashed praise of imprecision in Feyerabend 1981, p. ix.)

What can be done about inexact concepts? The tradition in mathematics and natural science has been to replace them with exact concepts. In recent times a new strategy has been advocated, namely that of accepting vague predicates and treat their ill defined extensions as fuzzy sets. (An exact predicate has an exact extension, i.e. one the membership of which is definite. An inexact predicate has a fuzzy extension, i.e. one the membership of which is not well defined; hence, given an individual, one may not be certain whether or not it belongs to the set. The mathematical theory of fuzzy sets has been invented to cope with such collections.) The decision to use fuzzy sets or abstain from using them in representing reality is a methodological one. The usual arguments are that reality itself is fuzzy, and that fuzzy concepts are respectable after all since we can speak about them in an exact way with the help of the theory of fuzzy sets. Let us deal briefly with these two arguments.

There is no evidence that reality itself is fuzzy or indeterminate. What is true is that certain exact concepts do not apply to some things: for example, the concepts of position, trajectory, and shape do not refer correctly to elementary particles. In such cases one introduces different but still exact concepts, such as that of position distribution instead of sharp position. Moreover all the successful factual theories have formalisms presupposing the theory of ordinary sets. In short, it is not that the world is fuzzy, but that our knowledge of it is imperfect (but perfectible). As for the claim that fuzzy sets have become respectable for being the subject of a mathematical theory, it is like saying that crime became honorable since the inception of criminology. Using fuzzy sets in modeling reality is a confession of defeat. The point is not to be able to speak exactly about inexactness but to reduce the latter and, if possible, to eliminate it altogether. Dirt must be recycled or eliminated, not be shoved under the carpet, let alone exhibited proudly. "Everything that can be thought at all can be thought clearly. Everything that can be said can be said clearly" (Wittgenstein, 1922, 4.116).

3.2. *Quality and Quantity*

Primitive and archaic thought are characteristically qualitative and analogical (Lloyd, 1966; Goody, 1977). By employing exclusively qualitative or dichotomous predicates, primitives and ancients were necessarily led to dichotomous or polar classings: cold and hot, heavy and light, clear and dark, near and far, wild and domesticated, good and bad. This mode of conception misses nuances and is apt to lead to a Manichean or a dialectical world view. Scientific and technological thinking, on the other hand, presumes that most properties come in degrees—of heaviness and speed, heat and nearness, excitation and value, and so on. Only in some backward branches of the social sciences and the humanities most thinking remains qualitative, hence polar or black and white.

True, a few properties are objectively qualitative, hence correctly representable by dichotomous predicates. Existence is an, perhaps *the* example: a thing either exists or it does not—there are no degrees of existence. (For the construal of existence as a predicate see Vol. 3, Ch. 3.) But most, perhaps all other properties, come in degrees that can be ordered or even assigned numbers. For example, there are different degrees of stability, including metastability and ultrastability. And, of course, there are infinitely many degrees of size, speed, probability, and what have you.

We cannot know a priori whether a given property is inherently qualitative or will turn out to be quantitative. We can only try to form a quantitative conceptualization of the given property and measure the latter to see whether we get more values than one (presence) and zero (absence). In any case modern science and technology since Galileo have adopted the methodological postulate that *every property, except for existence, can be quantitated.* Faith in this postulate has sustained all the investigators who have succeeded in quantitating properties previously believed to be imponderable. The postulate is confirmable but irrefutable for, should a given property resist our efforts to quantitate it, we may blame ourselves for our failure.

Having praised quantitation we must warn against the temptation to grade even complex properties by single numbers. Such oversimplification results in adopting IQ as an overall measure of intelligence, and increase in GNP as an overall index of progress. When such simple-minded quantitations are shown to be inadequate, irrationalists are confirmed in their mistrust of numbers. Better not give them this pleasure and recognize that in many cases a scalar will not do, but that a vector, a tensor, or a matrix may be needed.

Evidently quantitative knowledge, when available, implies qualitative knowledge but not conversely. Thus "distance" subsumes "separateness", "rate of change" subsumes "changing", and "probability" subsumes "possibility". If a quantitative pattern (law) has been found, its qualitative features can be extracted. Thus whether the evolution of a system is stable or unstable, can be found out theoretically only after its equation of evolution has been set up and tested—which equation involves numerical functions. (This is how Poincaré proved the stability of the solar system.) Therefore it is not true that the study of qualities always precedes that of quantities. The deepest qualitative knowledge is a byproduct of some quantitative knowledge. All of the social sciences could profit by this maxim; some of them, in particular economics and socioeconomic history, are already applying it.

The fundamentals of quantitation are these. Let S be a set of degrees or intensities of some property—objective degrees such as temperatures or subjective ones such as hotness. Postulate that S is simply ordered by a relation $\gtrsim$. (Hence if x and y are in S, then $x \gtrsim y$ or $y \gtrsim x$, and both statements hold only in case $x \sim y$.) In most cases this comparative concept is insufficient. We *quantitate* the given concept by mapping S onto a set of numbers in such a way that (*a*) each degree (member of S) be assigned a single number (one to one correspondence), and (*b*) the order in S be preserved, i.e. the numerical image of S reproduces the objective order in S.

(In other words the quantitation of S consists in introducing a mapping $M: S \rightarrow T$, where T is included in the real line, such that, for any x and y in S, $x \gtrsim y$ if and only if $M(x) \geq M(y)$. Thus "farther away than" will be quantitated as "at a greater distance than", and "hotter than" as "having a greater heat content than". In general such mapping is not unique: i.e. in principle there can be different quantitations of one and the same property. Think of the different temperature scales and the different modes of reckoning volumes of production. The choice among the various possibilities is dictated in some cases (e.g. length) by convenience, in others (e.g. temperature) by theory. If S is or is assumed to be nondenumerable, so must be its image T even if we do not possess the technical means for measuring the difference between two close members of T. If the map M is one to one, order preserving, continuous, and has a continuous inverse, it is called a *homeomorphism*.)

(The above procedure presupposes that we are given the entire set S of degrees of some property. This is sometimes the case. As a rule we build a quantitative concept regardless of empirical findings, and design observations or measurements in order to find some of the values of the function concerned. More precisely, we introduce a function $M: D \rightarrow T$, where D is in general a cartesian product of certain sets. At least one of these is a set of concrete things, such as bodies or societies, and at most one other factor is a set of units, such as the multiples and submultiples of the meter. For example, if we wish to reckon or measure distances between things in the context of relativistic physics, we introduce the distance function $d: P \times P \times F \times U_d \rightarrow \mathbb{R}^+$ obeying the usual distance axioms, where P is a set of physical objects, F that of reference frames, U_d the set of distance units, and $\mathbb{R}^+$ the set of positive real numbers. The mathematical theory of metric spaces leaves P uninterpreted and fails to include F and U_d. Any map $M: D \rightarrow T$ with the above characteristics is called a *quantitative predicate* or *magnitude*. See Bunge (1971, 1973a).)

(Qualitative predicates are particular cases of quantitative ones. Indeed the former are functions of the form $Q: D \rightarrow \{0, 1\}$ such that $Q(x) = 1$ iff x possesses the given property, and $Q(x) = 0$ otherwise. Once we have a set of magnitudes, e.g. those occurring in a mathematical model of a real system, we may focus our attention on certain global or qualitative features of the system. To this end we may need to *discretize* those magnitudes, i.e. to replace them with functions ranging over the integers. A common discretization is that of time, particularly when computers are employed. In this case differential equations are replaced with finite difference equations.

The discretization of a continuous system model is not always a trivial exercise. Sometimes it is suitable to discretize the state variables themselves, as when one stipulates that any values below threshold count as 0, and any above threshold count as 1. At other times one is interested in growth and decline rather than in absolute values. In such cases the rates are discretized, namely thus: the state of the variable is assigned the number 1 if its rate is positive, and 0 if negative. In this case the momentary state of the system is represented by an *n*-tuple of zeros and ones exhibiting the state of each variable: Glass (1975). In short, once again the qualitative features of the system are inferred from a quantitative model of it.)

Every real property is representable by at least one mathematical function, but the converse is false. Genuine quantitation obeys a methodological condition as well as a mathematical one. It must be accompanied by an indication that there are (direct or indirect, actual or potential) ways of effectively assigning (measuring) some values of the function in question. Otherwise quantitation will be judged phoney. Three examples should suffice. One is Herbart's phoney mathematical psychology. Another is the widespread belief, among contemporary philosophers, that propositions can be assigned probabilities, even though they are very discreet with regard to the method whereby such assignment is to be made. A third example of phoney quantitation is this. One can easily speculate that dreams have densities, and can imagine some postulates defining the dream density function—e.g. if dream *a* precedes dream *b*, then the density $d(a)$ is greater than the density $d(b)$. But this number game has no substance because we do not have the faintest idea how to determine effectively $d(a)$ and $d(b)$.

So much for quantitation, which we shall meet again when studying measurement (Ch. 11, Section 3.1). The two operations should not be confused, although they often are in the methodological literature (e.g. in Suppes and Zinnes, 1963). Quantitation is a purely conceptual operation, whereas measurement is empirical as well as conceptual. We can have quantitation without measurement but not conversely. For example, the concept of power exerted by organized crime in a given society may be quantitated, e.g. as the number of people whose economic or political activities are controlled by it, or by the annual volume of its business. However, since organized crime is supposed to be illegal, no reliable statistics can be compiled to measure its power. Still, this power is real, it can be roughly estimated, and one day it may be discovered. On the other hand it is impossible to measure in any objective way the probability of propositions, in particular hypotheses, so assigning them probabilities is a prime example of bogus quantitation. Although quantitation is different from measurement and precedes the latter, it is pointless unless measurement is possible at least in principle.

4. REPRESENTATION

4.1. *Conceptual Map*

Percepts tend to cluster into systems that map the body or the environment: those systems are the perceptual maps, which allow the animal to move around, make a living, and defend itself (Ch. 4, Section 3.1). Concepts also tend to organize into systems: some of them map the body, others the environment, and finally some (namely the theories in formal science) map nothing at all. All animals endowed with a central nervous system form perceptual maps, but only the higher vertebrates seem capable of forming conceptual maps, i.e. representations that overreach perception. Unlike the perceptual maps, the conceptual ones allow the animal to understand, forecast, and plan to some extent.

All conceptual maps are patterns of neural activity. However, some are externalized and thus become perceptible to other subjects: this is the case with diagrams, geographical maps, and systems of sentences or utterances. Whether or not externalized and thus visualizable or audible, conceptual maps summarize and systematize conceptual knowledge (or prejudice). And, whether or not they are accurate (true) representations of real items, they help us orient ourselves (successfully or not), as well as to act in the real world, in at least as effective (or misleading) a manner as perceptual maps.

Consider diagrams for a moment, and in particular the diagrammatic representations of a concrete system with known of conjectured composition, environment, and structure. About the simplest such representation is a diagram exhibiting the components (at a given level), the (relevant) environmental items, and the (main) relations among all such items: see Figure 5.8. Note that, although the diagram is perceptible, it is a conceptual or symbolic map not a perceptual one, if only because it may represent imperceptible things, such as an atomic nucleus composed of two nucleons held together by imperceptible links, such as fields. Note also that such a diagram is an extremely poor representation of any system: it summarizes only the minimal body of knowledge necessary to speak about a system. A stack of diagrams of the same type may provide a more detailed

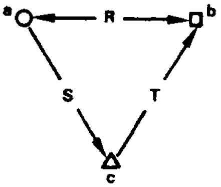

Fig. 5.8. Schematic representation of a system with two components, *a* and *b*, held together by the link *R*, and interacting with environmental item *c* via couplings *S* and *T*.

representation. But only a theoretical model of it—e.g. a system of differential equations—can give a detailed and deep representation. (We shall deal with theories in Ch. 9.)

Here are a few principles concerning the diagrammatic representation of material things:

(i) A diagram of a system should represent its composition, environment, and structure, either directly or in terms of properties. (A mixed diagram, containing arrows from things to properties or conversely, makes no sense because one and the same symbol, namely the arrow, is now made to denote a link or coupling, now the subject-predicate relation. However, such diagrams occur frequently in the literature.)

(ii) One and the same concrete system may be represented in alternative ways, and any such alternatives may or may not be equivalent. (They are so only if they can be obtained from one another via a topological transformation, i.e. one preserving the relations of vicinity.)

(iii) If two diagrams representing a given system are inequivalent, then they complement each other or one of them is more accurate than the other.

(iv) Diagrams are no substitute for theories. In particular, although they may suggest explanations, they cannot produce forecasts.

Like perceptual maps, conceptual maps can be analyzed as partial functions from stimulus events to neural events. (Cf. Ch. 4, Section 3.1.) But, whereas perceptual maps are limited to appearances, conceptual maps may represent reality, i.e. they may be subject-invariant. Think of a coin, its possible appearances to a subject, and the conceptual models of it. A single coin may appear to us in any one of infinitely many fashions—as many as its relative positions to ourselves, dynamic states, illumination conditions, etc. On the other hand only a finite number of conceptual models (e.g. geometrical, dynamical, and probabilistic) of a real coin can be built, none of which involves a subject.

Another difference between the two kinds of map is that, whereas perceptual maps resemble the represented objects, conceptual maps need not hold such a relation of analogy with their objects or referents. Think of a family tree, or of a system of econometric equations: unlike blueprints and geographical representations, such symbolic maps do not resemble their referents. Therefore the words 'picture' and 'reflection' do not describe them adequately. This suffices to write off naive realism (the copy or picture or mirror view of knowledge) as inconsistent with science and technology.

Contrary to naive realism, Helmholtz held that all our representations are symbolic and that even perceiving involves conjecturing. He wrote that representations are not copies or images but "only *signs* [symptoms] of external objects, and in no sense images of any degree of resemblance. [...] For a *sign* it is sufficient that it become apparent as often as the occurrence to be depicted makes its appearance, the conformity between them being restricted to their presenting themselves simultaneously; and the correspondence existing between our sensations and the objects producing them is precisely of this kind. They are signs which we have *learned to decipher*, and a language given us with our organisation by which external objects discourse to us—a language, however, like our mother tongue, that we can learn only by practice and experience" (1873, pp. 391–2).

Conceptual maps, and particularly factual theories, are indeed symbolic in some respect or other and so need not resemble their referents: Helmholtz's view is true of them. On the other hand it does not hold for perceptual maps: if the latter did not preserve at least roughly (some of) the relations among the stimulus events, we would be unable to move around and act in our environment. So, we accept Helmholtz's view for conceptual maps but not for perceptual ones. Incidentally, that view, though at variance with naive realism, is consistent with critical realism and even with materialism, for it presupposes the autonomous existence of the external world: Helmholtz insists that our ideas are signs of the latter. (This point was misunderstood by Lenin (1908, pp. 237ff.), who thought that if our ideas are only signs then the existence of external objects becomes doubtful.)

Naive realism is allied to mechanism, according to which the world is a mechanical system, so that every real thing can be pictured literally, i.e. described "*par figures et mouvements*" (Descartes). Since the inception of field physics we have learned that this view is overly optimistic; quantum mechanics has weakened further the mechanistic thesis, and the social sciences have never had any use for it. We know that only some physical objects, in particular medium sized mechanical systems, can be represented iconically, and even so only in a few respects. Electrons and photons, biopopulations and societies, cannot be diagrammed in detail: only symbolic systems can represent them. This does not mean that they are less real than stones, but that they have properties that cannot be grasped by perception. But, of course, the theories representing such things can be externalized by means of written symbols, and thus become vicariously perceptible.

Once a conceptual map has been drawn, written down, or taped, it becomes a cultural artifact, i.e. one that can be examined, modified or used by others. By becoming public, the map seems to acquire an existence of its own. But this is an illusion, for the drawing, printed page, or tape, would not perform any functions in the absence of brains. In other words, we have to do with three objects, and therefore three relations: the represented thing, its conceptual map in some brain, and the public manifestation of the latter. The relation between the latter and the thing it maps is a sort of product or composition of the relations artifact–brain, and brain–represented thing. See Figure 5.9.

4.2. *Discovery or Invention?*

If conceptual maps are not mere copies but instead symbolic constructions, then they must be creations like poems or musical scores and unlike photographs or tapes. Hence when exploring our environment we do not always make discoveries, as when finding a coin in a pocket, but sometimes we invent beforehand or at the same time that we discover, i.e. we discover a thing and invent a conceptual map of it. Thus Columbus was able to discover new lands for the Europeans only because he had previously

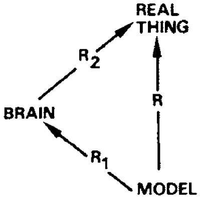

Fig. 5.9. The modeling relation R equals the composition of the model-brain and the brain-represented object relations.

formed a (rather inaccurate) conceptual map of the planet. When Harvey announced that he had discovered the circulation of the blood, he built a conceptual map of the human cardiovascular system complete with capillaries, which he had been unable to see. (So, the inimitable 17th century gossip John Aubrey (1949) was not totally wrong when he described Harvey as "Inventor of the Circulation of the Bloud"—as a result of which "he fell mightily in his Practize, and 'twas beleeved by the vulgar that he was crack-brained.") And when J. J. Thompson discovered the electron in 1898, he produced a conceptual map of it as a tiny electrically charged corpuscle. Others might have thought of cathode rays as jets of an electrically charged fluid: they would have missed discovering the electron.

Every important discovery is accompanied by the invention of a conceptual map of the object discovered. Moreover such a map is what makes the discovery important. Thus if an ignorant person finds a primitive tool and does not recognize it as such, he makes one more discovery among the many he makes every day. If the same object is found by a competent archaeologist, he may fit it into a conceptual map of a primitive society, and thus turn it into an important discovery. Likewise when an inventor imagines new uses of known things, assembles old units into new systems, or designs totally new systems, he forms conceptual maps. And some of his inventions may help make new discoveries. What holds for the invention of artifacts holds also for mathematical invention. Even the discovery of a previously unknown consequence of a set of premises, as in the proof of a theorem, is a creative process, for it leads to something new. A fortiori, the invention of new concepts, new theories, or new theorems is a creative process, and moreover an original one.

People are creative all the time: they keep on discovering or inventing things or ideas, mostly ordinary, sometimes extraordinarily clever or silly. But not all creations are original: many are rediscoveries or reinventions. A creation is said to be *original* when nobody but its creator knew it before. Obviously, original creations are not equally valuable: whereas some are good, others are bad and most are indifferent. Hence originality is not good in itself: only good originality is. Nevertheless some societies encourage originality in itself whereas others discourage originality and thus block progress—which is understandable, because novelty may threaten any rigid social order.

The notion of creativity is suspect in many quarters, in particular in empiricist philosophy and its psychological counterpart, behaviorist psychology. According to these doctrines all the organism can do is to admit environmental inputs, in particular pick up the information inherent in the environment. This environmentalist thesis would never have occurred to a historian: he knows that theories and machines are invented, not gathered like wild fruit or fish. Nor does the neuropsychologist have any difficulty in admitting creativity: to him it is the ability to form new neuronal configurations (Bunge, 1980a). This ability is partly innate, partly fashioned (or deformed) by education. A dogmatic education will systematically punish originality and encourage blind repetition, whereas a progressive education is supposed to free creativity—though it sometimes fails to promote it for fear of falling into dogmatism.

In general, all the higher vertebrates are creative, and a few individuals are original in some way or other. There is nothing mysterious about originality although there is much to learn about it. Every one of us has a peculiar brain composition and organization, and every one of us is subjected to environmental circumstances that differ somewhat from those of other individuals. (In particular, no two individuals have exactly the same protein composition and consequently can engage in exactly the same neurochemical reactions. And no two humans are treated exactly alike by their fellow humans or are presented with exactly the same opportunities and challenges.) In conclusion, there is a grain of truth in empiricism: we cannot escape our environment although we can modify it somewhat. And there is a grain of truth in rationalism as well: we create our own ideas, in particular conceptual maps—though not out of the blue. So, the whole truth contains a grain of empiricism and another of rationalism. However, it is not a mere merger or synthesis of the two, for each of them ignores the brain and that very particular environment which is society. We shall return to this subject in Ch. 15.

We value creativity but do not know the secret of it. Nobel laureate Linus Pauling was once asked how he had managed to propose so many good original ideas in so many different fields. He replied: "It's simple. You just have plenty of ideas, and cast off the bad ones". Yes, but how do you come by plenty of ideas, good or bad? And how do you manage to spot the bad ones? The first question is yet to be answered by the psychology of thinking; the second will concern us in Ch. 12.

5. CONCLUDING REMARKS

Perception gives us only perceptual knowledge, which is egocentric and limited to appearances. Only conceptual knowledge can be objective and deep: only conceptual maps give us a glimpse of things in themselves. (Cf. Schlick, 1925.) Still, conceptual knowledge is not independent of perception, which sets conception in motion and checks its products. This view, which can be found *in nuce* in Aristotle, is part of every critical realist epistemology.

Critical realism takes some elements from empiricism and others from rationalism but goes beyond both of them. Empiricism has always extolled the virtues of perception and rejected all concepts that did not originate in it. On the other hand rationalism has always praised the superiority of conception to the point of proclaiming the self-sufficiency of reason. Critical realism is a sort of synthesis of empiricism and rationalism, but it is not the only possible synthesis. Recall that Kant had managed to put together the negative aspects of empiricism and rationalism, by holding that we can have no experience without certain a priori intuitions, that things conform to human thought rather than the other way round, and yet we can know only phenomena, not things in themselves—all of which is out of tune with the realistic epistemology inherent in modern science and technology. (More in Ch. 15, Section 3.)

Although we pride ourselves on being the only animals capable of certain conceptual feats, such as building mathematical theories of the world, we still know very little about the psychology and neurophysiology of conceptual operations. This backwardness seems to have two main causes. One is our familiarity with such processes. (Familiarity may not breed contempt, but it certainly fails to spur inquiry.) The other is the belief that those operations could not possibly be studied scientifically—a belief nurtured by behaviorism. However, at last the scientific study of conception is under way since about 1960. Besides, we have learned to analyze many conceptual processes and have set up a number of rules for the correct performance of some of them, such as classification and deduction. Paradoxically, methodology is somewhat more advanced than descriptive and explanatory epistemology: we know how to perform certain operations correctly while having only very rough ideas of how we manage to do it.

Conceiving is anything but copying: it is a creative process going far beyond perception—which in the higher vertebrates is creative too, partly because it gets mixed with conception. We know very little about the mechanisms of conceptual creation, and this partly because of the empiricist tenet that every conception is a mere combination or elaboration of percepts. The classical examples are those of the centaur and the mermaid. The myriads of counterexamples supplied by logic, mathematics, science, technology, and the humanities, are merely ignored. Yet the invention of syllogisms, equations, grammars, the idea of an atom, and the wheel, owe nothing to perception. All we know is that conception is a brain process: we ignore its mechanism, and a fortiori the secret of originality.

CHAPTER 6

INFERRING

Conceptual knowledge can be augmented in either of two ways: by forming new propositions out of nonpropositional material (e.g. percepts), or by inferring new propositions from a set of known ones. We do the former, for instance, when producing empirical data and proposing conjectures to explain them. And we infer when, for example, drawing conclusions from a set of premises and leaping to generalizations on the strength of particulars. Both processes are equally important in all fields of inquiry. However, the importance of inference is often underrated by those workers who, misled by empiricism, believe that all they have to do is collect solid facts and abstain from committing what they regard as the capital sin of the intellect, namely jumping to conclusions. But, of course, those who do not jump do not overcome any hurdles, and so do not participate in any original cognitive venture.

As in the case of propositions, it is possible to adopt either a psychological or a philosophical (and in particular logical) viewpoint concerning inference. That is, we may regard it either as a brain process without paying attention to its validity, or as a timeless relation between propositions and focusing on its validity with total disregard for its neurophysiology. In line with our program of fusing the scientific and the philosophical approaches to inquiry, we shall adopt both viewpoints. However, we shall spend far less time on the former than on the latter because we know very little about the physiology and psychology of inference.

Every inference is either deductive or nondeductive. The former is demonstrative, the latter nondemonstrative and at most suggestive. Deduction is of course the central theme of logic, which has become a separate branch of mathematics. We shall have little to say about it. Nor shall we spend much time on nondemonstrative inference, in particular induction and analogy. Not that induction and analogy are unimportant, as the rationalists claim: they are pervasive, though perhaps not more so than intuition. Moreover they can and must be studied, though not with the hope of coming up with exact rules or methods, such as the rules contained in works on inductive logic and the much-vaunted inductive method.

Likewise love and hate deserve being studied, though not with the aim of producing scientific love or scientific hate.

The above does not entail that all nondemonstrative inferences are worth the same, namely little, let alone nothing. Nondeductive inferences, like guesses, can be wild or educated, gratuitous or compatible with data or theory. But whether or not they happen to be lucky is for tests, not for an a priori discipline, to decide.

1. FROM SPONTANEITY TO FORMALITY

1.1. *Natural Reasoning*

The psychobiological investigation of reasoning patterns is a recent development which is yielding few but important results on the thinking habits of children, primitives, and adults living in modern societies. (See Nisbett and Ross, 1980.) We shall make a quick review of some typical findings.

In all inference we must assume some premises, even if we do not know whether they are true, if only for the sake of argument, in particular to find out whether such assumptions lead to acceptable consequences. This detached attitude is not universal. The natural thing to do is either to accept or to reject a premise rather than to examine it with a purely cognitive concern. Entertaining or examining assumptions without committing oneself a priori to them is not done in early infancy and may be a rather recent historical acquisition. At least, the historical record does not seem to go farther back than a few centuries before our era.

In particular, children do not seem to be able to form conditionals, i.e. propositions of the form "If A then B", until about age 3, and this only when prompted by their teachers. Moreover when they do form a conditional they presuppose its antecedent A to be true: it is only much later that they can envisage conditionals with false antecedents or antecedents with unknown truth values. Likewise nonliterate peoples seem incapable of forming such conditionals. (Cf. Luria, 1976.) In short, hypothetical reasoning comes rather late or not at all: it seems to be peculiar to an advanced stage of culture.

Not surprisingly, argument too comes rather late. Piaget (1955) found that children go through two stages with regard to argument: quarrelling and argumentation proper. The former consists in a clash of views, and it is the mental equivalent of fighting. Genuine argument, which exhibits reasons, motives, or causes, does not appear until age 7. (But, presumably, the majority of such rational arguments are formally invalid.) Another result of Piaget's studies (1955) is that, before the ages of 7 or 8, children may reject self-contradictions but they do not often notice contradictions between opinions voiced successively: their body of beliefs does not form a system. Between 7 and 8 they start noticing and rejecting contradictions, thus building gradually belief systems or world views. (Whether this process is universal or peculiar to advanced cultures, is not known.)

Once a person has attained this rational stage she tries to eliminate contradictions within her body of beliefs by discarding some of them. However, if such contradictions persist—if the person cannot give up one of the theses in conflict—the individual tries to "rationalize" them. If she fails, she feels a psychological discomfort. And, as long as she feels such discomfort, she acts so as to reduce "cognitive dissonance", much in the same way that she tries to reduce other imbalances, such as hunger. One way of reducing dissonance is to avoid situations where the individual is forced to choose between the horns of her dilemmas. Social intercourse is at the same time a source of cognitive dissonance and a vehicle for eliminating it by introducing new knowledge. The greater the dissonance, the stronger the social pressure to reduce it. (Festinger, 1957).

Although the theory of cognitive dissonance does not seem to have been established experimentally (Chapanis and Chapanis, 1964), casual observation confirms that ordinarily we abhor contradictions but, when we cannot get rid of them, we atone for them in some way or other. For example, the contradictions inherent in every religion lead some people to claim that they are mysteries, others to patch them up with further absurdities. And the contradictions between dogma and action—e.g. preaching Christian love and waging war in the name of it—could always be solved, or at least absolved, by penance, fines, or service of the church's worldly interests (Tuchman, 1978).

Another recent finding of cognitive psychology concerns multiple reasoning in educated adults. It is the hypothesis that human thinking, far from being sequential, is multiple, in that it consists in a number of parallel threads grouped around a main sequence, which is the one within the conscious area: "Awake or asleep, a number of more or less independent trains of thought usually coexist. Ordinarily, however, there is a 'main sequence' in progress, dealing with some particular material in step-by-step fashion. The main sequence corresponds to the ordinary course of consciousness. It may or may not be directly influenced by the other processes going on simultaneously" (Neisser, 1963). Introspection confirms this conjecture.

There is a century-old debate on primitive mentality. The early anthropologists noted the great disparities between the savage mind and ours: the poverty of its conceptual stock, its difficulty in generalizing, its incapacity to entertain hypotheses, the clumsiness of its reasoning, and the general lack of interest in abstraction. Being often adjuncts to imperialist expeditions or colonial administrations, some of those anthropologists tended to attribute such backwardness to an inherent biological inferiority. The early liberal reaction to this racist claim was to deny that there is such a thing as the savage mind, and to hold instead that there is only less information: reason is universal, knowledge is not.

Later studies have shown that each of the two contenders held a grain of truth: there is primitive mentality but it has to do with schooling not race. The primitive tribesman cannot perform complicated conceptual operations because he has a poor conceptual kit and does not handle pencil and paper—but he can learn. In particular, knowing only a few numbers, he cannot keep track of any extensive stock, let alone perform calculations, e.g. of distances or speeds—but he can learn.

The anthropologist Sylvia Scribner (1977, p. 486) proposes the following generalizations on the basis of studies concerning proficiency in solving logic problems. "1. *In all cultures*, populations designated as 'traditional' or 'nonliterate' have just somewhat better than a chance solution rate across all types of problem material. [. . .] 2. *Within each culture* there is a large discrepancy of performance between schooled and nonschooled. The major jump seems to occur at levels of education as low as two to three years of school. [...] 3. With schooling, there is little *between-culture* variation in performance for the cultures studied. Grade, rather than society, is most determinative of performance". In short, although actual reason is not universal, potential reason is, and it can be actualized by schooling. So, there is a chasm between the savage mind and the civilized mind, but it is being crossed all the time with the spreading of schooling.

Even in civilized societies most adults seem to reason fallaciously most of the time as soon as they go beyond practical matters. Thus in a typical experiment only 9 percent of the subjects concluded correctly that the premises "All P are M" and "All S are M" do not entail anything about the relation between Ss and Ps (Chapman and Chapman, 1959). In another typical experiment, only half of the subjects drew the correct conclusion (namely "C is worse than A") from the premises that B is worse than A and C is worse than B (cf. Mayer, 1977). When faced with a set of data, the typical undergraduate conconcts a single hypothesis, is reluctant to consider falsifying data, and fails to consider alternative hypotheses (Johnson-Laird and Wason, 1977). Moreover, casual observation shows that resistance to give up a hypothesis in the face of adverse data mounts with the importance of the hypothesis in one's world view.

Typically, the layperson and occasionally also the scientist and the technologist operate with biased samples—usually collections of items that happen to be noticed and remembered—rather than with random samples; they detect, or fail to detect, covariations suggested by prior beliefs; they tend to expect and forecast what they wish to happen; they tend to pooh-pooh exceptions and criticisms; and generally they adopt beliefs on the strength of first impressions, authority, or fashion. (For these and other fallacies see Nisbett and Ross, 1980.)

The conclusion is obvious: logic is extremely artificial. However, it is not much more so than cooking, building, literacy, or reckoning. Right thinking does not come more naturally than reading or plane piloting: it must be learned. Cognitive psychologists have known this for half a century, and they have also known that most college students will consistently incur fallacies of all kinds unless they have taken courses in logic or in higher mathematics. However, knowledge does not go easily across disciplinary barriers, and so the vast majority of college students graduate without having been exposed to either logic or higher mathematics. And once habits of thought have been acquired it is hard to change them. Thus whereas the person who has been trained in mathematics tends to form clear ideas and reason correctly, the person who has been trained in the humanities is often tolerant of inexactness, and the individual who has had a theological or in general ideological training cannot help thinking in opposites and prefers criticism and debate over constructive reasoning.

1.2. *Formal Reasoning*

Spontaneous or natural reasoning is tacit, undisciplined, and often invalid. Formal reasoning is, by definition, explicit, regimented, and valid. It is formal because its validity is independent of the meaning of the premises and the conclusion. It is explicit in that it involves only explicitly stated premises and inference rules. It is regimented in the sense that it is subject to (though not directed by) principles or rules (e.g. those of the predicate calculus). And it is valid in that, when its premises happen to be true, its conclusions are true as well. (A rule of inference can be construed as a truth preserving function from n-tuples of propositions to propositions.) So far, only deductive inference has been formalized. There is no reason to hope that other types of inference (e.g. inductive and analogical) will follow suit, for they are content-dependent, i.e. their success depends on the nature of the case.

In ordinary language we often confuse reasons with causes: 'because' can be interpreted either as a causal relation (by cause of) or as a logical relation (by reason of). At first sight this is a confusion: reasons are conceptual objects whereas causes are events. (Bunge, 1959a.) However, on second thought there is something to be said for such conflation: ultimately every reason *is* a brain process and therefore a cause of some other bodily process. So, although not all causes are reasons, every reason is a cause. Still, reasons, to be valid, must comply with certain logical requirements. For example, the truth of A is logically a sufficient reason for upholding "A or B"—but the cause for making the latter claim may be the need or wish to rope B into the argument. Hence, although neurophysiology is ultimately to describe and explain reasoning, it cannot justify it. (Analogy: sociology can explain crime but not condone it.) Only logic can justify reasoning by showing that it fits accepted canons of inference.

The most basic inference pattern is substitution, which is subject to the principle of (invariance under) substitution of variables (terms) or of entire propositions. If in any formula $F(\ldots x \ldots)$ the variable y is substituted for x, then that formula implies $F(\ldots y \ldots)$. For example, $x^2 + x = 0$ and $x = y - 1$ jointly imply $y(y-1) = 0$. The most familiar method for solving systems of linear equations, and the most popular method for evaluating integrals, use the rule of substitution.

The simplest of all the rules of inference involving two premises is of course the *modus ponens*: B is an immediate consequence of A and $A \Rightarrow B$. Combining this rule with the rule of substitution (exchanging A for $\neg B$ and B for $\neg A$) yields the *modus tollens*: $\neg B$ and $A \Rightarrow B$ jointly entail $\neg A$. Many a scientific paper violates either rule. Indeed, a rather common fallacy is this: $A \Rightarrow B$ and B, hence A (or $A \Rightarrow B$ and $\neg A$, hence $\neg B$). This error is in fact committed when a hypothesis is declared true because some of its consequences have been confirmed.

Needless to say, the detectives in good mystery stories do not commit such fallacies. A typical example is this. After some inquiries the inspector gathers all the people involved in the crime and presents them his premises:

1. Every criminal has a motive and an opportunity. (Law of criminology.)
2. The butler had both a motive and an opportunity. (Empirical datum.)

3. Nobody except the butler had both motive and opportunity. (Plausible hypothesis.)

All three premises are necessary and sufficient to draw the conclusion that the butler did it. This proof can be obtained by *reductio ad absurdum*: Suppose someone else, call him or her C, did it. Then C had both motive and opportunity. But this contradicts premise No. 3. Hence C is identical with the butler. The argument is an example of valid *hypothetical* reasoning, for it involves two hypotheses going beyond the hard datum 2, namely 1 and 3.

To be sure, we are not always given conditionals: sometimes our task is to prove them. In mathematics, to prove that A implies B one can often assume A and check whether it entails B (i.e. whether "$A \Rightarrow B$" is a tautology). For, if it does, then a fortiori $A \Rightarrow B$. (A second method is to assume $\neg B$ and find out what this entails concerning A. If it entails that $\neg A$, the conditional has been established.) In factual science and technology the method for establishing $A \Rightarrow B$ is quite different. One enforces A and checks whether B obtains. If it does, the conditional is confirmed but not proved, for it may well happen that only the favorable cases were observed during the given experimental run. If B does not obtain, the conditional has been refuted—or so it seems. In general, there are no rigorous proofs of factual statements.

Strictly speaking, mathematical proofs are not absolutely rigorous either, and this simply because there are no absolute (definitive) standards of rigor. Given any proof, it is likely that it can be improved on, if not right now, then in a few years or centuries. Moreover, logical standards are changeable. The history of the calculus is littered with proofs that were regarded perfect at one time but turned out to be defective in some respect or other. However, there is a big difference between mathematical proof and factual confirmation: whereas the former can *in principle* be rendered unassailable relative to the prevailing standards of rigor, factual confirmation remains in *principle* assailable, not only because its premises are uncertain but also because it involves plausible rather than demonstrative inferences. Caution: the fallibility of a mathematical proof and of a factual confirmation does not entail that we must ultimately resort to some extrinsic sanction such as consensus. It only suggests that further research may be needed.

Our discussion of deductive inference has not depended upon the notion of truth. To be sure, we did characterize a rule of deductive inference as a truth-preserving function from n-tuples of propositions to propositions. However, this condition is needed to check the validity of any proposed rule of inference, not to perform any deductions. (Thus the obviously false premises "All men are immortal" and "Donald Duck is a man" entail rigorously "Donald Duck is immortal".) It is just as well that deducibility should not involve truth, for often (*a*) we do not know whether our premises are true (but are just trying them out), and (*b*) our premises are at best half-true.

Logic, the theory of deduction, is concerned to save consistency, not to guarantee truth. We want consistency for the following reasons: (*a*) a contradiction entails any proposition, and is thus a source of unwanted proliferation (conceptual cancer); (*b*) consistency is necessary (though not sufficient) for a set of propositions to form a system allowing one to jump safely from one component to another. Logic (or rather metalogic) can diagnose consistency and inconsistency but is impotent to advise what to do in the face of inconsistency. To be sure, if a set of premises turns out to be inconsistent then we can strike off some premises to obtain one or more contradiction-free subsets of premises, but logic will not tell us which, if any, such subsets is formed by true premises.

For example, the set of premises $\{A, B, A \Rightarrow \neg B\}$ is inconsistent. In fact, the 1st and 3rd imply $\neg B$, which contradicts the 2nd; and the 2nd and 3rd imply $\neg A$, which contradicts the first. The three minimal surgeries yielding consistent sets of premises are:

(i) Drop A, leaving $\{B, A \Rightarrow \neg B\}$, which reduces to $\{\neg A, B\}$.
(ii) Drop B, leaving $\{A, A \Rightarrow \neg B\}$, which reduces to $\{A, \neg B\}$.
(iii) Drop $A \Rightarrow \neg B$, leaving $\{A, B\}$.

In the case of mathematics all three subsets may be correct though of unequal or even null interest. If we are to choose among them it will be on grounds of richness or beauty, economy or applicability. If the premises are factual, compatibility with the available evidence and with other theories may indicate which of the three subsets, if any, is the best (truest and deepest) set. But it may well happen that all three are inadequate—or that the evidence is so hazy that neither is completely ruled out by it. In conclusion, *pace* Rescher (1976), there is no a priori general theory of plausibility that could help us choose among the above contradiction-free subsets.

Consistency is an absolute desideratum relative to each particular body of knowledge, in particular theory. It is not equally desirable with regard to the totality of knowledge at a given moment: if overall consistency were required at every moment, then no rival views would be tolerated, and consequently we would be unable to correct any errors. So, inconsistency is a fact of life and we must learn to eliminate it (by uprooting errors) rather than to avoid it.

Dialectical philosophers hold that contradiction is not only unavoidable but also desirable to keep things moving, for contradiction among ideas (and even among facts) is the source of all change. The evidence goes against the universality attributed to the genetic power of contradiction. Indeed the history of ideas shows that, whereas some conceptual contradictions have indeed promoted progress (by calling for strenuous efforts to surmount them), others have resulted in stagnation or even regress. Here is a random sample of counterexamples to the dialectical thesis. (*a*) The contradiction, within the Pythagorean school, between its tenets concerning rational numbers and the discovery of irrationals (such as the square root of 2), brought the efforts of the members of the school to a halt. (*b*) The contradiction between the subjectivist and the frequency interpretations of probability has produced no new results except for confusion. (*c*) The contradiction between the wave and the particle interpretations of the quantum theory has held back work in the foundations of the latter. (*d*) The contradiction between classical mentalistic psychology and behaviorism kept psychology from making any breakthroughs for decades. (*e*) The contradiction between individualism and holism in social science is still bogging it down. The moral is clear: Contradictions, when protracted, are unhealthy because they generate sterile and acrimonious debates rather than new ideas or new experiments. Contradiction does not generate anything: at most it may motivate some people to overcome it.

We often need to estimate the degree of agreement or disagreement between two sets of propositions, e.g. between two scientific theories, or two ideologies, or a scientific theory and an ideology. Actually we need two different measures, one for the degree of agreement between two sets of propositions, and another for the degree of compatibility. The two measures must be radically different because two sets of propositions may be quite different yet compatible (e.g. an atomic theory and a sociological theory), or similar yet mutually incompatible (e.g. two rival theories).

(Consider two sets of propositions $P=\{P_i | 1 \leq i \leq p\}$ and $Q=\{q_j | 1 \leq j \leq q\}$. We define the *degree of agreement* between P and Q as the fraction of the number of propositions they share, i.e.

$$A(P,Q)=(1/p+q)\cdot|P \cap Q|.$$

The degree of *disagreement* between P and Q is defined as

$D(P, Q) = 1 - A(P, Q)$. The values of A and D are comprised between 0 and 1. Such values can be computed only for finite sets of propositions. In the case of theories we may take the sets of their postulates; in the case of rival theories it pays to enrich the postulates with all the standard theorems. Two different presentations or organizations of the same theoretical material are supposed to agree fully with one another, i.e. $A(P, Q) = 1$. On the other hand two genuinely rival theories must share some but not all their propositions, i.e. $0 < A(P, Q) < 1$.)

(Let us now introduce the concept of degree of compatibility between two sets P and Q of propositions. They will be totally incompatible if every member of P contradicts each component of Q—an extremely unlikely case. We abbreviate 'p_i is incompatible with q_j' to '$p_i | q_j$', and correspondingly 'p_i is compatible with q_j' to '$\neg(p_i | q_j)$'. We now define the *degree of compatibility* between P and Q as the fraction of the number of pairs of compatible propositions:

$$C(P, Q) = (1/pq)|\{\langle p_i, q_j \rangle \in P \times Q \mid \neg(p_i | q_j)\}|.$$

The dual is of course the degree of *incompatibility* between P and Q, namely $I(P, Q) = 1 - C(P, Q)$. The values of the two measures are comprised between 0 and 1. If $C(P, Q) = 1$, P and Q are fully compatible, even if they do not agree at all, whereas they are totally incompatible if $C(P, Q) = 0$. Any value between these extremes indicates incomplete compatibility.)

Can logic help us obtain new knowledge? Nearly all of the 17th and 18th century philosophers derided logic for its alleged impotence to do so. They demanded instead that a logic of invention and discovery be instituted. Although such a logic was never born, it was much praised. And in the meantime the contempt for logic blocked its advancement. (You do not farm well a land that you despise or hate.) Logical investigations were resumed two centuries later by mathematicians, but the calumny that logic is useless to advance knowledge still remains. Even after mathematical logic was well established, a distinguished philosopher such as Schlick (1925) ignored its role in research and suggested that, since science studies only facts, and there are no negative facts, it should make do with a negation-free logic. This is a correct inference from the thesis that scientific research is just the collecting of trivial facts. It falls down as soon as one realizes that there is no science without conjecturing and arguing, which involves counterconjecturing and counterarguing. Certainly there are no negative facts, but negation (a "positive" brain process) is part of every inquiry process. Statements of the form "A is not B" are just as important as those of the form "*A* is *B*"; i.e. identity and inclusion are not more important than difference and exclusion.

When a mathematician, a theoretical scientist or a technologist prove a new theorem, they produce genuine new knowledge with the help of the logical theory underlying (presupposed by) the theory or theories they employ. (And, since the most common types of proof are by *reductio ad absurdum* and by counterexample, negation is usually involved in such deductive processes.) To be sure, logic does not supply any substantive premises: it acts as midwife rather than parent. Nevertheless its intervention is necessary to produce or control the new results. If deduction did not yield new knowledge we would not care to perform it and, in particular, we would not care to build or use theories proper, all of which are hypothetical-deductive systems.

It is often rejoined that the conclusion of a deductive inference is "contained" or "included" in the premises, so it is not actually new. This is sophistry. In the first place not all the conclusions of a deductive inference occur among the premises. Thus "All *A* are *C*" follows rigorously from "All *A* and *B*" and "All *B* are *C*" (as well as from "All *A* are *X*" and "All *X* are *C*"), but is not contained in these premises. Likewise one gains new knowledge, by deduction, from the data that $a > b$ and $b > c$, namely $a > c$.

Secondly, even if all deduction were merely unpacking, it still would supply new knowledge: if nobody knew the conclusion before it was drawn, then the conclusion was not an item of knowledge—it only became one. What is true is that we may *feign* that the conclusion exists (formally, not epistemically) the moment the premises (and the underlying logic) are laid down. Likewise the value of a continuous function at a given point is "given" by a certain formula containing the values of the function and all its derivatives at some other point, but the former is unknown as long as the computations indicated by the formula have not been performed.

In short, deduction is a prime tool of inquiry, for it allows us to explore the (a priori unknown) consequences of our assumptions and definitions. And, because deductive reasoning is formalizable and subject to explicit rules, one is justified in calling *hypothetico-deductive method* the pattern of reasoning consisting in assuming, deducing, and checking. No other type of inference is formalizable and subject to explicit rules, and therefore capable of becoming the nucleus of a method. In particular, although we all use plenty of intuition, analogizing and induction, there is no such thing as the *method* of intuition, or analogy, or induction. There are only philosophical tracts on such ghostly subjects.

Finally, are there things we cannot reason about? All we know is that, every so often, we come up against certain limits to knowledge that are subsequently overcome. Thus the Eleatic philosophers believed change to be contradictory and therefore contrary to reason; and, being rationalists, they declared change to be illusory. Thus a moving arrow was said *to be* and *not to be* at a given place at a given time. Hegel kept this archaic mode of thought and admitted the Eleatic thesis that change is contradictory, but claimed that this only calls for the dialectical mode of thought. Bergson chose the other horn of the ancient dilemma: he claimed that only intuition can grasp change—whereas science, which is rational, cannot. We see no contradiction in change. Instead of saying that the arrow is, and is not, at a given place at a given time, we say that it moves with such and such instantaneous velocity through a given place. We replace being with becoming as the basic category, and use the differential calculus to reason about change. One man's limits to reason is another's challenge to improve reasoning.

2. PLAUSIBLE REASONING

2.1. *Analogical Inference*

The most basic judgment we can form about a collection of items is that they are, or fail to be, similar in some respect(s)—i.e. that they are analogous or disanalogous. Judgments of analogy underlie a number of judgments of other types, in particular collecting or grouping (Ch. 5, Section 1.2) and inductive generalization (Section 2.2). We make them all the time in daily life and in all fields of inquiry. Here is a tiny random sample of analogies that have been fruitful at one time although they ended up by blocking further research: set–collection of things, gas–solute, electric current–fluid current, light–sound, economic competition–natural selection, optics–mechanics, and rumor propagation–epidemics. We tend to remember only the fruitful analogies. The list of misleading analogies, if it could be drawn, is likely to be more impressive.

Analogical inference is based on analogical judgment but goes beyond the latter: from the fact or assumption that two objects are analogous in some known respect(s) it "concludes" that they *may* be analogous in some other unknown respect(s) as well. Thus organicists, likening society to the human body, conclude that the workers, being the muscles of society, ought to obey the brain of society, namely its ruling class. And Copernicus, likening the solar system to a monarchy, argued that, just as the monarch is surrounded by his vassals and courtiers, so the sun must be at the center of the solar system. Both are of course implausible reasonings, not plausible ones. They are faulty because they rest on wrong analogy judgments: society is not like an organism, and the solar system is not like a monarchy. On the other hand Aristotle's classical example of analogical reasoning, namely "Gills are to water what lungs are to air", was plausible and fruitful. It was so because it rested on two genuine analogies: gill—lung and water—air. A necessary condition for a plausible and fruitful analogical inference is then that it rests on genuine analogies. We should therefore elucidate the rather vague notion of analogy.

There are several ways of exactifying the notion of analogy, and each is suitable for a given set of problems. One of them involves the modeling of the analogous objects as sets. In this case one can elucidate a number of analogy strengths, from mere some–some correspondence to homomorphism, to isomorphism or perfect similarity. (Cf. Bunge, 1973b, Ch. 6.) A second method is to count the number of properties shared by the analogous things: see Vol. 3, Ch. 2. A third applies when the things concerned are systems, i.e. objects with a definite composition, environment, and structure. We proceed to elucidate this notion (Bunge, 1981b).

Consider two systems, each modeled qualitatively by a triple *composition–environment–structure* (Vol. 4, Ch. 1). Each component of this triple is a set. In comparing the triples representing two systems we compare sets (of components, environmental items, or relations). Therefore we must start with the concept of similarity or analogy of two sets. We stipulate that two sets are similar with respect to a third set if they overlap with the latter. More precisely, if A, B and C are nonempty sets, then ***A is similar to B with respect to C*** if, and only if, $A \cap C \neq \varnothing$ and $B \cap C \neq \varnothing$. We can now define the concept we want:

Let s_1 and s_2 be two concrete systems with known compositions, environments, and structures. Then:

(i) s_1 and s_2 are *substantially analogous* iff their compositions are similar, i.e. if there is a natural class or species that has a nonempty overlap with those compositions;

(ii) s_1 and s_2 are *environmentally analogous* iff their environments are similar, i.e. if there is a natural class or species that has a nonempty overlap with those environments;

(iii) s_1 and s_2 are *structurally* (or *formally*) *analogous* iff their structures are similar, i.e. if there is a family of relations that has a nonempty overlap with those structures. (In particular, two systems are *nomologically analogous* if they share some laws.)

All organisms are substantially analogous, if only because they all contain DNA molecules. Fish and marine mammals are environmentally analogous. The human hand and the bat wing are structurally analogous (homologous).

The above concepts may be quantitated with the help of the following concept of degree of similarity between sets. If A and B are sets intersecting a third set C, then A and B can be said to be fully analogous with respect to C if both have the same number of elements of kind C, i.e. if the cardinalities of $A \cap C$ and $B \cap C$ are the same. The degree of dissimilarity between A and B with respect to C is then measured by the difference between $|A \cap C|$ and $|B \cap C|$. More precisely, we stipulate that

$$d_C(A, B) = \frac{||A \cap C| - |B \cap C||}{\max\{|A \cap C|, |B \cap C|\}}.$$

Therefore the *degree of similarity between A and B with respect to C* may be taken to equal the complement of $d_C(A, B)$ to unity, i.e. $s_C(A, B) = 1 - d_C(A, B)$. The values of the degree of relative similarity are comprised between 0 and 1. If A and B contain no C's, then $s_C(A, B) = 0$. But if there are just as many C's in A as in B, then $s_C(A, B) = 1$ even though they are not the same individuals. For two sets to be similar in the given respect C they just have to contain at least one member of kind C.)

By applying this concept of similarity between sets to our previous notions of systems analogy we obtain the concepts of degree of substantial, environmental, and structural analogy. Moreover, by adding all three and dividing by 3 we get the concept of *degree of total analogy*. Finally, we can invert the process to obtain the qualitative concepts of analogy in terms of the quantitative ones: Two systems are (*a*) *analogous* iff their degree of total analogy is greater than 0; (*b*) *weakly analogous* iff their degree of total analogy, though nonvanishing, is close to 0; (*c*) *strongly analogous* iff their degree of total analogy is close to 1.

A proposition of the form "A and B are analogous" is *true* if, in fact, the degree of analogy between A and B is greater than 0. However, truth is not enough, for it may be deep or shallow, fruitful or barren. The judgment of analogy will be *superficial* if the systems in question are weakly analogous. (*Example*: the brain–computer analogy.) The judgment will be *deep* if the systems in question are strongly analogous. (*Example*: the man–ape analogy.) However, even deep analogies may not be fruitful. The fruitfulness of an analogy depends not only upon its degree but also on the problem at hand and the brain that uses it. Many people had noted the analogy between man and other primates; in the Middle Ages it was a common belief that monkey was a fallen man. However, it took a Charles Darwin to use this analogy to place man and ape in an evolutionary perspective.

Because the fruitfulness of an analogical inference depends on the actual degree of analogy as well as on the imagination of the user, there can hardly be a general theory of analogical reasoning. The most we can do is to formulate some useful methodological (not logical) rules, such as:

R1. Use only deep analogies—i.e. make sure that the degree of (substantial, environmental, structural, and if possible total) analogy is significantly greater than 0.

R2. Regard all analogies as heuristic devices that may have to be discarded eventually.

The first rule is obvious: weak analogies lead nowhere or, worse, they may block inquiry. For example, the analogies between brain and hydraulic system, electrical network, telephone exchange, or computer, are not only extremely weak: they have also misled uncounted workers in neuroscience and in psychology into studying technological gadgets rather than living brains. (More in Vol. 6.)

The second rule is justified as well: even if initially fruitful, an analogy is no substitute for an investigation of the peculiarities of the thing of interest. Thus the quantum-classical analogies were initially useful as rough guides, but ended up by obscuring the originality of the quantum theories as well as the nonclassical nature of their referents (Bunge, 1973a). And the information-theoretic metaphors employed in biochemistry, molecular biology, and genetics, helped crack the genetic "code" but they are now blocking the way to an understanding of the mechanism of protein synthesis and, in general, the way "genetic information" is locked in nucleic acids. (More in Vol. 6.)

Because rigorous reasoning is nonanalogical, scientific papers in advanced science and technology are not supposed to resort to analogical reasoning—not even when proposing analogies. If they do, they do so inadvertently. On the other hand analogy and analogical inference are rampant in the popularization literature, for they are (wrongly) assumed to convey technical ideas to the lay. (Actually they skirt the problem of conveying them.) And, since most philosophers have no access to the original scientific or technical literature, they sometimes get the impression that analogy, far from being just a heuristic trick and a pedagogical prop, is of the essence of science and technology. (For the quaint thesis that scientific theories are analogies or metaphors, see Black (1962) and Hesse (1966).) Occasionally there are also more serious motivations for this view, or analogism. One is fictionism, or the doctrine that we cannot know what and how things really *are* but at most what they are *like*, so we should present our hypotheses and theories as stating only that things behave or appear *as if* they were such and such. (Fictionism has its roots in Kant, was sketched by Nietzsche, and worked out by Vaihinger (1920).) Another root of analogism is the attempt to present science as no better than religion: just as (according to Aquinas) we can know God only by analogy with worldly entities, in particular ourselves, so science would know the world only by analogy with our experience.

In short, analogies and analogical inferences are indispensable tools of inquiry. But analogies can be superficial or deep, and analogical inferences can be misleading or fruitful. It is therefore necessary to assess the respect and degree in which an analogy holds, and to check the conclusion of an analogical argument. And we must not conclude to analogism from the fact that analogy is pervasive, if only because it is not more so than other categories.

2.2. *Statistical Inference and Hypothetical Reasoning*

Induction is, of course, generalization from known (or partially known) instances. Every higher vertebrate performs inductive inferences, and scientists and technologists are no exception. Many of the generalizations, true and false, we form and use in daily life are inductions. (Perhaps most of them are generated by only a handful of cases.) And every time we evaluate the performance of hypotheses, theories, methods and plans, we formulate inductive judgments. So, induction occurs sometimes in the inception of general constructs and always in their validation.

We distinguish the following types of *inductive inference.*

(i) *First degree induction*: from instances to low level generalization. *Pattern*: "All A's up to the nth were found to be B's. Hence it is likely that all A's are B's." *Example*: All the measured values of the speed of light in a vacuum are the same to within experimental error. Hence it is likely that all light waves in a vacuum have the same speed.

(ii) *Second degree induction*: from low level generalizations to higher level generalization. *Pattern*: "Law L holds for every member of a family of sets up to the *n*th. Hence it is likely that law *L* holds for every member of the family." *Example*: The theory of evolution holds for all studied species. Hence it is likely to hold for all biospecies.

(iii) *Statistical specification*: from population to sample. *Pattern*: "The observed fraction of *P*'s in the population *U* is *p*, and *S* is a random sample of *U*. Hence it is likely that the fraction of *P*'s in *S* be near *p*." *Example*: The last census showed that 10 percent of the population are unemployed. Hence it is likely that about 10 percent of the population of Medianville, which is pretty representative, are unemployed.

(iv) *Statistical generalization*: from sample to population. *Pattern*: "*S* is a random sample of the population *U*, and the observed fraction of *P*'s in the random sample *S* of *U* is *p*. Hence it is likely that the fraction of *P*'s in *U* be near *p*." *Example*: In a random sample of college students amounting to the one-hundredth part of the total student body 1 percent were found to be original thinkers or doers. Hence it is likely that the corresponding percentage in the whole student population be about 1 percent.

Note the following traits common to all of these inference patterns. First, neither is wild: they all proceed from supposedly sound (checked) premises. Second, neither leads to new concepts; in particular, all the theoretical concepts occurring in the conclusions appear also in the premises. Third, neither is conclusive or demonstrative: they are not of the form "*A*, hence *B*", but rather "*A*, hence it is likely that *B*", with no specification of the degree of likelihood. Thus room is made for failure of the inferential process. For instance, in the example of (iii) Medianville, though representative on the whole, may be particularly lucky, or unlucky, at the moment the inference is drawn—e.g. because it happens to host an industry that has suddenly boomed or slumped. And in the example of (iv) the student sample, though representative on the whole, may be exceptionally rich or poor in talented students at the time the sample is drawn—e.g. because talented students tend to concentrate in certain colleges.

Consequently neither of the above inference patterns can be erected into a rule or principle, e.g. the "principle of induction", more often praised or criticized than formulated. The conclusions of all such plausible reasonings are just as hypothetical as their premises. Consequently they call for further testing. Besides, neither the premises nor the conclusions occurring in inductive inference are enough: we also need higher level hypotheses, which cannot be generated by studying particulars, if only because they contain concepts that are far removed from observation. The task of induction is not to generate such high level hypotheses in step by step processes, but to take part in their empirical tests, as will be seen in Ch. 12.

In addition to the above four patterns of inductive inference we shall mention four kinds of *hypothetical reasoning*.

(i) *Weak modus ponens*: weak detachment of consequent upon weak assertion of conditional or of antecedent. *Patterns*: (*a*) "If p then q, and 'p' is verisimilar. Hence 'q' is verisimilar"; (*b*) "'If p then q' is verisimilar, and p. Hence 'q' is verisimilar." (*c*) "'If p then q' is verisimilar, and 'p' is verisimilar. Hence 'q' is verisimilar." *Example*: Heavy smoking is likely to cause lung cancer. John is a heavy smoker. Hence John is likely to catch lung cancer."

(ii) *Weak modus tollens*: weak rejection of antecedent upon strong or weak assertion of conditional and weak or strong negation of consequent. *Patterns*: (*a*) "If p then q, and '$\neg q$' is verisimilar. Hence '$\neg p$' is verisimilar". (*b*) "'If p then q' is verisimilar, and $\neg q$. Hence, '$\neg p$' is verisimilar." (*c*) "'*If* p then q' is verisimilar, and '$\neg q$' is verisimilar. Hence '$\neg p$' is verisimilar." *Example*: It is likely that philosophy flourishes only in freedom. Now, there is no freedom in Dogmaland. Hence it is unlikely that philosophy flourishes in Dogmaland.

(iii) *Strong reduction*: weak assertion of antecedent upon assertion of consequent. *Pattern*: "If p then q, and q. Hence maybe 'p' is true." *Example*: brain injuries cause intellectual deficits. Now, Peter has recently converted to a mystical doctrine. Hence it is possible that Peter suffered a brain injury.

(iv) *Weak reduction*: weak assertion of antecedent upon assertion of consequent and strong or weak assertion of conditional. *Patterns*: (*a*) "If p then q, and 'q' is verisimilar. Hence it is possible that 'p' is true." (*b*) "'If p then q' is verisimilar, and q. Hence it is possible that 'p' is true." (*c*) "'If p then q' is verisimilar, and 'q' is verisimilar. Hence it is possible that 'p' is true." *Example*: Famines are likely to cause political unrest. Now, there was a revolution in *A* during period *B*. Hence it is possible that there was a famine in *A* during *B*.

Like inductive reasoning, plausible hypothetical reasoning is educated rather than wild, as well as inconclusive: its conclusion is at best another conjecture worth being investigated. But, unlike inductive reasoning, plausible hypothetical reasoning may proceed from premises containing transempirical concepts. For this reason it occurs not only in the early stages of empirical research and in the testing stage but in all stages of scientific and technological inquiry.

Inferring from symptoms, or indicators, is a common species of hypothetical reasoning and, in particular, of weak reduction. Thus since all infections cause an abnormal count of white blood corpuscles, we tend to attribute the latter to some infection; however, it may have a different cause, such as cancer of the bone marrow. Likewise we tend to attribute criminality and drug addiction to poverty, but some times it is caused by alienation.

Most indicators in the life sciences and in the social sciences are ambiguous, i.e. they occur in hypotheses of the form *If A or B then C*, where '*C*' denotes the observed variable adopted as an indicator of *A* or *B*. Therefore it is advisable to employ a whole battery of indicators in order to narrow down the set of possible causes. But the only effective way of removing the uncertainties in inferences from symptoms is to employ functional relationships between symptoms and causes. Thus the barometer gives an unambiguous reading of atmospheric pressure because it is built on the law of the linear relation between atmospheric pressure and barometer height; and it can be used to give an unambiguous value of the altitude on the strength of the exponential law relating altitude and atmospheric pressure.

Plausible reasoning, whether analogical, inductive, hypothetical, or of some other kind, cannot be regimented any more than intuition or insight can. First, because it depends essentially on the nature of the case. Second, because it depends on the talent of the subject to notice or conjecture relevant features or patterns. Third, because one and the same set of data is compatible with any number of alternative hypotheses: Figure 6.1. In sum there can be no *logic* of plausible reasoning.

However, plausible reasoning can be controlled. Actually it is being controlled by mathematical statistics, not by philosophy. Indeed, the tasks

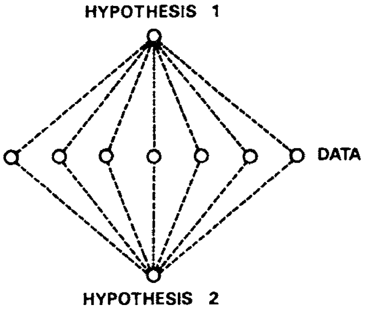

Fig. 6.1. At least two different (rival) hypotheses are compatible with any given set of data.

of that discipline are not only to help collect, screen and organize data, but also to help compare the latter with hypotheses in order to evaluate both (usually the hypotheses). But, of course, mathematical statistics produces neither raw data nor the hypotheses accounting for them: it is a device for control not generation. For example, it tells us that statistical generalization and specification are plausible only if the sample is random and its size not too small: otherwise violent fluctuations around the frequency will be observed. (Sample size, though essential, is less so than randomness.)

We all pay lip service to mathematical statistics but few of us succeed in avoiding committing statistical fallacies such as the gambler's fallacy. This is the belief that every segment of a random sequence (or every random sample of a population) must have the same properties as the entire sequence (or population). Thus if in coin tossing the inexperienced gambler gets five heads in a row, he may be inclined to bet that the next flipping will produce a tail: he believes that there must exist a force producing a deviation that will cancel the previous deviation from the long run 0.5 frequency. This fallacy is committed not only by gamblers but also by a disquieting large fraction of scientific researchers (particularly in psychology and social science); moreover, they exhibit undue confidence in early trends, overestimate significance, and offer causal explanations for any local discrepancies instead of paying attention to sample variability (Tversky and Kahneman, 1971). This finding shows how inadequate our statistical education is, and it suggests that the teaching of probability and statistics should start earlier than usual, perhaps in primary school.

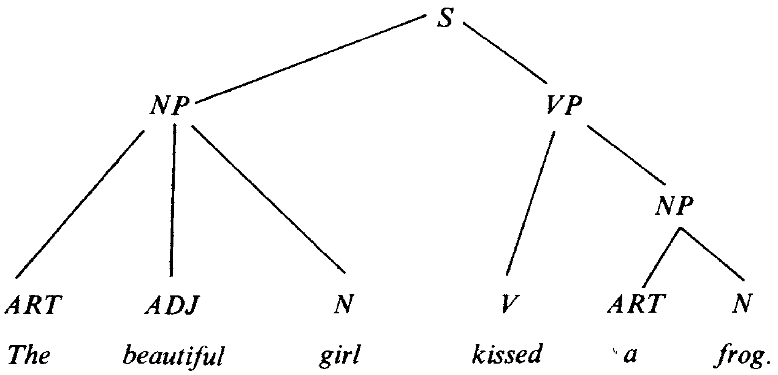
3. Discussing

3.1. *Analysis and Criticism*

Can we learn from discussing ideas, e.g. from analyzing them and arguing about them? Rationalists reply in the affirmative, and some of them claim that analysis, criticism and argument are the very best cognitive methods. The schoolmen of all times assent because they hope to extract all the knowledge locked in allegedly canonical and infallible texts. The linguistic philosophers, because they regard ordinary language as the repository of wisdom. The dialectical philosophers, because they believe that new ideas can be generated only by the clash of old ideas (or the clash between ideas and facts). And the critical rationalists, because they are interested primarily in the weeding out of false ideas. On the other hand, empiricists deny all this: to them only experience, in particular observation, can give us new knowledge, whereas discussion is unprofitable and perhaps even (as Comte said) frivolous. Who is right? Once again it will turn out that each of the contending parties holds a grain of truth.

To analyze a complex object, such as a system, is to exhibit its components, environment (or context), and structure (or organization). The analysis can be partial (decomposition into subsystems) or total (decomposition into ultimate or elementary components). It can be empirical (e.g. chemical) or conceptual (e.g. logical). In every case the components, the (relevant) environmental items, and the relations or links holding the system together are identified and classed. A few examples will show the gist and scope of such procedure.

Example 1. Structural analysis of a sentence. Look at the tree diagram representing the surface structure of the English sentence *The beautiful girl kissed a frog.*



The species or lexical categories are ART (icle), ADJ(ective) and N(oun); the genera NP (noun phrase) and VP (verb phrase). One and the same object, namely the sentence S, is conceived of as a system and analyzed on two levels: subsystems (made up of objects on the genus level, NP or VP), and elementary objects (belonging to species such as N and V). The analysis uses then a word systematics that is taken for granted, and which differs somewhat from language to language. (Thus Latin lacks the ART species.)

Example 2. Logical analysis of the proposition expressed by the sentence in Example 1. A possible analysis is this:

For some x, x is a frog and b kissed x, where

> $b=$ The y such that y is a girl and y is beautiful at fixed place p and time t.

Example 3. Mathematical analysis of proposition in Example 2. Every one of the logical categories occurring in the given proposition can be analyzed further, i.e. into deeper concepts. For example, the predicate "frog" can be construed as a function from the set of all reptiles (or all vertebrates, or all animals, or all organisms) to the set of all propositions contining that predicate. Likewise the predicate "beautiful" can be analyzed as a function from the cartesian product of the set of all objects, the set of all places, and the set of all times, to the set of all propositions containing that predicate. The connective "and" can be analyzed as a function from pairs of propositions to propositions. The particularizer "Some" can be analyzed as "Not-for-all-not", where "all" and "not" are primitives, or in a more sophisticated way. Likewise the descriptor "the y such that" can be analyzed *à la* Russell or as in Vol. 2, Ch. 9.

In all three cases the "environment" (context) of the system being analyzed has been taken for granted: the English language in the first, the predicate calculus in the second, and mathematics in the third. And every analysis has presupposed some body of knowledge about such contexts—in particular a knowledge of basic categories such as "noun", "predicate", and "function". The logical analysis (Example 2) has also presupposed a bit of factual knowledge, which on closer examination turns out to be dubious. In fact, that analysis presupposes that beauty is absolute (independent of the beholder); it also presupposes that place and time are absolute (independent of the reference frame). If relativized, the predicate turns out to be of degree 5 or higher, not 3.

In performing each of the three analyses we had to invest a certain amount of knowledge. But we gained some new knowledge too. For, even supposing that we knew the components of the system before analyzing it (since we fashioned it ourselves), we did not know the kind or type to which each of them belonged, or how they were related to one another. To be sure, the output has been puny by comparison with the input. However, the same can be said of all kinds of analysis. Think of the analysis of a function as an infinite series, or the analysis of a chemical compound into atoms, or the analysis of a society into economic, political, and cultural subsystems. In all these cases the knowledge investment (data and general principles) is far greater than the knowledge produced. But what is important is that *(a)* analysis *can* produce new knowledge—empiricism notwithstanding, and (*b*) analysis is only *one* of the ways of gaining new knowledge from available knowledge—rationalism notwithstanding.

Analysis can be valuable, but not all analysis is. Thus linguistic analysis, as practised by Wittgenstein and his followers, and hermeneutic analysis, the daily fare of lawyers and popular among theologians, political ideologists, and contemporary German philosophers, are ambivalent. The former because it is shallow and sometimes misleading: it makes no use of logic—let alone mathematics or science—and is limited to examining the use of ordinary language locutions. Its results are usually very modest, as must be expected from a "philosophy without tears" (Russell). And sometimes they are grotesque, as when Ryle (1954) concluded, from an examination of what he called 'the grammar of the word *perceiving*', that seeing and hearing are not states or processes, hence not something to be located, inspected and measured. Correct conceptual analysis calls for more than a mastering of one's dialect: it requires substantive knowledge and fine analytic tools, often mathematical ones.

As for hermeneutics, or the interpretation of texts, it has three uses. One is to arrive at an understanding of the original text, another is to evaluate current actions or ideas in the light of some code, and a third is to help us understand or modify current events. In the first case, the hermeneutic analyst attempts to explain the given text in contemporary terms and to place it in its original cultural context. This enterprise is as risky as it is useful, for it forces the authors of the past to think and write like ourselves.

A second use of hermeneutic analysis is to examine certain actions or ideas to find out whether they conform to some doctrine or code. It is standard procedure in law. The basic inference pattern is this: *A holds or does B. Now, B is compatible (or incompatible) with canonical text C. Hence A is right (or wrong) on C.* The doctrine or code itself is not questioned. So, the analysis is useful if the canonical text happens to be correct or just, but it can be noxious if the text is wrong or unjust. In any case this kind of hermeneutic analysis does supply some knowledge—e.g. that A did say or do something fitting (or clashing with) a certain canonical text. Moreover, if what A said or did is judged as correct or just on a different standard, then that piece of hermeneutic analysis will suggest that the canonical text is wrong on the given point, which in turn may elicit its reform.

Finally, a third kind of hermeneutic analysis is to try and understand what happens to and around us in terms of some text written hundreds or even thousands of years ago for different people in different circumstances. Such analysis is worthless or worse, as it involves a distortion of the text, the contemporary events, or both—for otherwise the events could not possibly fit the text. Needless to say, this use of hermeneutic analysis is common among ideologists wishing to confirm their beliefs or to use them to praise or condemn some of their contemporaries. Arguing with analysts of this kind is unlikely to produce new knowledge, for their intention is apologetic, not inquiring.

Conceptual analysis can be regarded as a means for uncovering composition, environment or structure, or as part of criticism. And criticism is of two kinds: *apologetic* (or in defense of a belief system) or *inquiring* (or aiming at spotting error). In turn, inquiring criticism can be *negative* or *constructive*. The former stops when error has been found and exposed as such. Constructive criticism goes farther, to error correction. The proofreader, the dedicated teacher and the productive investigator, technologist, and manager are constructive critics. On the other hand the literary critic and the art critic, as well as the typical book reviewer, are negative critics. Negative criticism is easier and therefore more common than constructive criticism: (*a*) it bears on something that has already been set up (by oneself or someone else), and (*b*) the denial of a proposition has better chances of being true than its assertion. (*Example*: if one states that the current world population is exactly 4 billion, he shall be in error. The denial of that statement is true—a cheap truth, for it gives no positive information.)

Criticism is necessary in all fields of inquiry because an aim of all inquiry is truth, and no research is free from error. We are bound to make some erroneous assumptions, observations, computations, or inferences; we are bound to employ vague concepts or inadequate methods; and we are bound to disregard some variables and overrate others. Any such error may spoil a research project if it goes undetected and uncorrected, but none of them counts in the end if spotted and repaired in time. This is why criticism is tolerated, nay encouraged, in science, technology, the humanities, and enlightened management and politics. For the same reason criticism is discouraged elsewhere, particularly in institutions devoted to the maintenance of dogma, authority, or privilege. Thus churches meet criticism with excommunication, the armed forces with court martialling, and some political parties with expulsion.

The epistemology of science and technology involves methodological (though not systematic) skepticism, a critical attitude that spares nothing excepts the ideals of objectivity and rationality. Everything, from theories to data, from methods to institutions, can become the object of scientific doubt or technological redesign. Science and technology have institutionalized skepticism: "Organized skepticism involves a latent questioning of certain bases of established routine, authority, vested procedures, and the realm of the 'sacred' generally" (Merton, 1973, p. 264). For this reason science and technology are bound to clash sooner or later with all other institutions, for these usually demand faith and loyalty.

The critical attitude, essential in science, technology and the humanities, seems to be rather uncommon elsewhere, and tolerance of criticism quite recent. There must have been dissenters in all human societies, but they are likely to have been persuaded or suppressed by persons wielding authority. All societies have belief-enforcing mechanisms, and only a few tolerate open criticism, particularly of basic social policies. However, in most cases no repression is required to exact conformity, for most people are ready to believe or do what they are told.

In short, criticism is necessary to clarify ideas and eliminate errors. However, criticism should be neither overdone nor overrated. It should not be overdone because it may kill good ideas in the bud, when they are still hazy and have not shown their worth. This is why scientists and technologists resent hasty criticism: they know that every idea is born incomplete and defective, and it should be allowed to develop before being shot down. And criticism should not be overrated (as Popper (1963) does) as the main moving force of every intellectual development because, before an idea can be analyzed, criticized, or rejected, it must have been thought up by somebody. After all, it is easier to destroy than to construct. Just as the history of art is that of creative artists, not of art critics, so the history of science and technology is that of original scientists and technologists, not of thinkers specializing in criticizing as severely as possible every tentative solution to a problem. The main moving force of the advancement of knowledge is not contradiction or criticism but inventiveness in facing and solving new problems. Criticism is the control of the process of inquiry, not its energy source. Like every other control it must be handled with care, for whereas in some cases criticism uproots error, in others it just gives vent to neophobia: witness the editorial process in learned journals. (Cf. Garcia, 1981.)

Criticism is necessary in all conscious endeavors, whether cognitive or practical, but not all criticisms are equally valuable. The best criticism is constructive: one engages in it not to show off (as is the case in carping) or for sheer *Schadenfreude*, but for the love of truth or usefulness. It is part of the self-correcting mechanism of inquiry, be it in science, technology, or the humanities. (Ideology and pseudoscience lack such a mechanism. If only for this reason it is mistaken and dangerous to hold—as Feyerabend (1975) has done—that science is no better than magic or religion.)

To conclude this section. Criticism is neither the mark of rationality (Popper) nor the life of science (Poincaré), but a component of all inquiry. Therefore, to disregard or stifle criticism is to give free rein to dogma and charlatanry—whereas to exaggerate its importance is to forget that it is a means not an end. The clash of ideas is important to clarify and evaluate them, but not more important than the ideas themselves. And there is no such thing as the critical (or dialectical) *method*, i.e. a set of rules for sparking off clashes of ideas, examining them critically, or evaluating them, let alone for generating new ideas superseding the old ones. There are only a few general principles of argumentation, such as "Stick to the subject", "Do not tolerate self-contradiction", and "Concede defeat when it comes". But we are already trespassing on the next section.

3.2. *Controversy*

Controversy is criticism rendered public, at least within some inquiring community. Publicity has the great advantage that many can join in to contribute to the clarification of issues and the resolution of conflicts. But it also has the disadvantage of inflaming noncognitive passions and thus makes admission of error more difficult.

The history of religion, political ideology, and philosophy, is often presented as an unproductive sequence of indecisive fights over firmly held beliefs. In contrast, that of science and technology is usually presented as a progressive sequence of discoveries and inventions—all of them "positive" contributions—wherein controversy plays no important role. (See Agassi, 1963.) Moreover we are often told that controversy is a mark of vanity or, worse, an indicator of the immaturity of an epistemic field. Thus Kuhn (1970, pp. 6–7): "In a sense [. . .] it is precisely the abandonment of critical discourse that marks the transition to science".

There is much truth in the above. In fact controversy is less frequent, and far less indecisive, in science and technology than elsewhere; and it is less conspicuous in the older branches of science and technology than in the newer ones. (Thus there are far more and more acrimonious controversies in psychology or sociology than in mathematics or chemistry.) Moreover, a sort of preliminary dogmatism is needed in science and technology, where one always starts by taking a certain body of knowledge for granted, never questions all of it, and replaces some of its components only if forced to. Kuhn (1963) has pointed out the positive function of "dogma" in scientific research, holding that, as a consequence, resistance to change is normal and on the whole healthy. However, since the inquirer regards his background knowledge as only a launching pad that may have to be modified, it is incorrect to call it a dogma. His may be called *methodical dogmatism*, the companion of the *methodical skepticism* discussed earlier and the enemy of systematic dogmatism. Indeed the "preconceptions" or even "prejudices" that a scientist or technologist inherits are always on probation and may be modified or discarded altogether, some for having been shown to be erroneous, others for having lost value or interest. All scientific and technological (and also humanistic) knowledge has a built-in obsolescence. On the other hand ideological (in particular religious) dogmas are untouchable, and so are the principles of school philosophy. Those who reject them are branded as heretics and perhaps also punished. On the other hand those who criticize accepted scientific or technological principles or practices may be regarded as unorthodox but, if proved right, are hailed as revolutionaries or benefactors.

Just as excess controversy is a sign of immaturity of an epistemic field, so too little controversy may indicate senility, for every radically new idea is bound to elicit controversy if published. The healthy state of an epistemic field is one where most research is done along traditional (but fertile) lines, some explores radically new (but promising) approaches, and another argues the merits and demerits of either. No special control mechanism is needed to produce or keep such division of labor: most inquirers are naturally inclined to follow a successful tradition, only a few are capable of staging revolutions, and the controversy lovers, so numerous in the humanities, are scarce in science and technology. In fact most scientists shy away from controversy either from timidity or because they believe the positivist legend that only "positive" findings matter. As for technologists, they are even more circumspect though for different reasons: the design of a new artifact may be an industrial or military secret or, once in production, controversy over it could hamper its marketing or use. Not many technologists are as public spirited and courageous as Ralph Nader.

There is controversy in nearly every contemporary research field. Sometimes controversy indicates the inadequacy of, hence dissatisfaction with, some received ideas or practices; at other times it indicates resistance to revolutionary innovations; and at still other times, clash with vested cultural, political, or economic interests. Whatever else it may indicate, controversy shows the interest aroused by the issue; in turn interest is a (weak) indicator of importance. (Nobody except Byzantine philosophers or theologians gets excited over trivia.)

Here is a quick sample of recent controversies in science and technology. (*a*) The controversy over the physical interpretation of the mathematical formalism of the quantum theories has continued unabated since the inception of these theories. The main rivals are the positivist (or Copenhagen) and the realist (or objectivist) interpretation. (*b*) The controversy between the "big bang" hypothesis of the origin of the universe and the steady state theory died out in the mid 1960s. However, a few astronomers do not accept either position and are looking for alternative explanations of the redshift of distant galaxies. (*c*) Although most biologists admit the fact of evolution, not all of them believe that it has been gradual or that it has proceeded exclusively on random mutation and natural selection. (*d*) Depending on which traits are taken to be peculiar to *Homo sapiens*, the origin of modern man is assumed to date back either 50,000 or 300,000 years ago. And whereas some investigators postulate a single line, others conjecture that there have been at least two (one of them the Neanderthal man). (*e*) Psychology is torn by the nature–nurture, the behaviorism–cognitivism, and the mind–body controversies. (*f*) In the social sciences the old battles between individualism and holism, as well as between idealism and materialism, are still reging—and these are only two out of dozens of spirited controversies. (*g*) Technologists are divided over the hardness of technology (advanced, appropriate, or soft) that should be used, over the accountability of technologists to society, etc. (*h*) Military experts debate endlessly over the merits and demerits of intercontinental missiles, neutron bombs, and other weapons.

None of these controversies is likely to be barren provided they are conducted with some rationality and in freedom. As it is, controversialists cannot help employ persuasive means—in particular rhetorical tricks and showmanship. As for freedom of inquiry, which includes the freedom to criticize and publish criticism, as well as to hold unorthodox views, it varies across research fields and from society to society, but it is never complete. Some groups, even within the scientific and humanistic communities, wield more power than others, and so are better equipped to impose their own views. In science most of the time there are illustrated despotisms, but occasionally they stifle legitimate debate. For example, physicists are nowadays less tolerant to unorthodox views than social scientists.

Scientific and technological controversies eventually come to an end if they are purely technical, i.e. if they do not involve any philosophical or ideological principles. They come to an end in any of several ways. Here are some: (*a*) one of the parties exhibits a decisive observation, calculation, or technique; (*b*) a synthesis of the two rival views is proposed, that incorporates the good points of each; (*c*) a third party enters the controversy and wins the day; (*d*) the issue is forgotten for lack of interest; (*e*) censorship stops the discussion and imposes the official view: (*f*) one of the parties brandishes a bunch of computer printouts and announces 'The computer says so'.

There should be no doubt as to the efficiency of criticism to weed out error and thus clear the way for new ideas and even novel approaches. Thus Galilei's polemical works were no less important, for the revolution which he spurred, than his scientific ones. However, we should not follow Popper and overrate the power of criticism to advance knowledge, for the thrust of scientific and technological research is invention and discovery, not argument. In these fields controversy is the salt not the roast.

Besides, scientific or technological controversy, if overdone, can have negative effects. One is that it obfuscates the parties involved, which makes them lower their standards of rigor and objectivity, as well as harden whatever dogmatism may infect them. Controversialists are finally won by the desire to win the argument rather than to find the truth. Another negative effect of controversies is that they often contribute to the fragmentation of a research field. This happens whenever each party sees only one of the sides of a question, with its legitimate problem system, but fails to see the other. One example is the century-old debate, mostly mute, between the biologists who seek laws and those who try to establish life histories or phylogenetic lines. Far from being competing research lines, these are mutually complementary and should be merged instead of being kept separate.

The philosopher can participate in scientific or technological controversies either by taking sides or as an arbitrator—particularly if he feels that the contending parties are talking through one another and should cooperate rather than fight. And the historian's task is neither to hush up controversy for fear that it will spoil his story of cumulative induction, nor—*pace* Agassi's brilliant allegation (1963)—to read the history of science and technology in the same way as that of ideology or philosophy, i.e. as a story of schools and their controversies. In science and technology controversy is healthy provided it is conducted honestly and in freedom, but it is seldom the main occupation of researchers. The main task of scientists is to unveil the world, that of technologists to design means to control it.

4. CONCLUDING REMARKS

One way of gaining knowledge is by making observations or measurements, another is by forming and checking conjectures, and a third is by ferreting it out of available knowledge, i.e. by inference. All inference is from some nonempty set of premises—data, hypotheses, or definitions. True, the set of logical truths can be said to follow from nothing, i.e. to be entailed by the empty set of premises—provided rules of inference are granted. *Ex nihilo nihil fit.*

Inference yields new propositions but not new concepts. Thus if we know the sum and the difference of two numbers, we can find out what those numbers are—provided we have already the notions of number, addition, subtraction, and division. Therefore it is mistaken to call quarks, genes and mental processes 'inferred entities': they are hypothesized not inferred.

We need both rigorous (valid, deductive) and nonrigorous (invalid, nondeductive) inference in all fields of research. Even the most austere research, if fruitful, will beget logically illegitimate brain children—new concepts not defined in terms of the known ones or new propositions that do not follow from the known ones. No one type of inference is more productive than any other type. New concepts are not the product of inference, and hypotheses obtained by rigorous deduction (e.g. in theoretical physics) need not be truer or deeper than conjectures born of sheer insight.

Inference has been regarded as a surrogate of experiment (Rignano, 1923). To be sure some reasoning is thought-experiment and it may save us or, on the contrary, suggest real experiment. (Think of planning chess moves or of playing around with mental images or scale models of molecules, buildings or armies.) But no reasoning can replace experiment: there is no substitute for empirical data. And no experiment can replace reasoning: every experiment is designed and interpreted rationally. Reasoning and experiment are therefore mutually complementary, not interchangeable.

A hasty induction has led empiricist philosophers to proclaim the *inductivist* thesis that every generalization, or at any rate every true (or warranted or believable) generalization is inductive: that we start every inquiry into matters of fact by studying individual cases, and conclude it by summarizing our findings into inductive syntheses, never proceeding from hypothesis to observation. By contrast rationalists, seduced by the success of pure mathematics, uphold the *deductivist* thesis that induction is unimportant or incidental: that we start every inquiry with some hypothesis or other, and find out by deduction what it commits us to; experience would come, if at all, at the very end, and its power would be negative rather than positive: it refutes but does not verify.

We endorse neither inductivism nor deductivism but do adopt elements of each. In our view research is sparked off by problems, not by observation or by hypothesis. Observation poses problems or checks hypotheses, but it is neither the only source of problems nor the only way of testing hypotheses. All inquiry except the most trivial involves deduction mingled with plausible inference, and the latter includes induction but is not restricted to it. Confirmation and refutation are seldom conclusive—except, again, in trivial matters. And induction supplies only relatively modest hypotheses and no theories at all. However, induction is involved in the checking of every generalization. The empirical worth of a hypothesis or theory is gauged not only by its resistance to refutation attempts but also by its positive confirmation or inductive weight (the set of data it accounts for) as well as by its theoretical support (the set of theories with which it jibes). But all this will be discussed at length in Ch. 12, after having studied the notions of problem, hypothesis, theory, explanation, forecast, and their kin.

PART III

EXPLORING AND THEORIZING

CHAPTER 7

EXPLORING

From an epistemological viewpoint, to live is to face and solve problems. We face practical problems, such as that of finding the next meal, and cognitive problems, such as that of finding out the nutritive value of a given food. We tackle some cognitive problems for pleasure and others because their solution may help us solve practical problems. Likewise we handle some practical problems for their own sake and others because their solution may allow us to pose or solve cognitive problems. All higher vertebrates handle cognitive problems, and man excels at inventing new problems on top of those he meets in daily life. And yet traditional epistemology has paid little if any attention to problems, the starting point and object of every inquiry. As a result we know very little about the biology, psychology, and logic of finding and solving problems.

In this chapter we shall peek at exploratory behavior and shall identify some problem sources. We shall also study the ways cognitive problems are selected for investigation. In the process we shall meet two concepts that in a way are mutually complementary: those of intuition and method. This will take us to the question of approaching a problem, which is part of every research. Finally we shall unveil the form and content of problems. None of this will transform the art of formulating problems into a science, but it may advance the art and help us understand the most fascinating of all cognitive operations, namely research.

1. EXPLORATORY BEHAVIOR

1.1. *Psychobiology of Problems*

Many animals seem endowed with an innate exploring or investigating ability (Pavlov, 1927, p. 12). This is the capacity to recognize and tackle problems of various sorts—e.g. "What is that?", "Is that edible?", "Is that friend or foe?", "Where may I find water?", "Can I negotiate that obstacle?", and the like. What is peculiar to man is not the capacity to recognize and tackle problems but that of formulating them consciously and explicitly, and investigating them methodically rather than by blind trial and error. Also peculiar to man, at least over the past 10,000 years or so, is interest in purely conceptual problems removed from practical concerns, and pleasure in questioning solutions as well as in conceiving new problems.

A number of biologists seem to go farther and claim that all surviving organisms have "solved" successfully the "problems" posed by their environments, and that such "solutions" (which others call 'adaptations') constitute genuine inventions. Some even say that biological evolution is a problem solving process. And a few have gone as far as to hold that all a scientist or an engineer can do is to imitate, adapt or improve such "inventions". However, most biologists, if pressed, will adopt a sober attitude and own that all that is metaphor: that, although all organisms face challenges, not all challenges are or pose problems. And most psychologists will agree that only some animals, namely those capable of learning (and therefore knowing something), handle problems proper.

An animal may be said to *face a problem* when it feels the need or wish for some additional piece of knowledge—which of course presupposes that it did have some knowledge to begin with. The problem is *cognitive* if its solution might satisfy a purely cognitive need or wish. It is *practical* if its solution might be employed as a means for attaining a practical goal. In particular, a practical problem is *moral* if its solution might guide behavior that could affect the welfare of some conspecifics.

Like any other distinctions, these should not be transformed into detachments. Thus finding out that a certain drug has serious toxic side effects poses the cognitive problem of finding antidotes to it, or the moral problem of whether it should be banned. And appreciating the miseries of underdevelopment poses the cognitive problem of how best to contribute to alleviating them, as well as the practical problem of implementing whatever measures have been designed to solve those practical problems. In sum, sometimes sheer curiosity or wonder, and at other times need or want, sparks off inquiry, which in turn may result in discoveries or inventions capable of satisfying either. There is then no incompatibility between the culturalist and the economicist hypotheses concerning the root of inquiry: they are mutually complementary rather than exclusive.

An animal engaged in solving a problem explores: it explores the environment or itself, in particular its own store of knowledge and skills. However, not all exploratory behavior is problem solving: only *purposeful exploration* is. Thus the automatic and random exploration conducted by animals incapable of knowing anything is not of the problem solving kind:

not knowing anything, they have no knowledge gaps to fill. And it is doubtful that we are justified in assigning inquiring automata the ability to solve problems, for they have no purpose or design of their own: any intention they may have has been built into them by their manufacturers. They are not really inquiring machines but machine aids to human inquiry. As Duncker (1945) put it, "A problem arises when a living creature has a goal and does not know how this goal is to be reached".

Purposeful exploration, be it of the environment or of oneself, is triggered by the need or wish to cope with novelty, experience new situations, perceptions or feelings, or conceive new ideas. Neuropathology suggests that the arousal of curiosity and the drive to inquire are states or events in certain subsystems of the brain, in particular the mammillary bodies, the limbic system, and the hippocampus. In fact when any of these systems is damaged by accident or by drugs, in particular alcohol and marihuana, the questioning ability is seriously impaired. This impairment is extreme and irreversible in Korsakoff psychosis, characterized by lack of curiosity and initiative: the patient is apathetic, lacks initiative, and places himself at the mercy of his environment. He is good only at repetitive tasks: he cannot face new problems, let alone seek them.

A Korsakoff patient does not cope with novelty but at least he can be aware of it. In deep sleep or coma we may not even perceive, let alone seek, new stimuli: we are not alert. The alertness center of the mammalian central nervous system is the brainstem reticular formation (Moruzzi and Magoun, 1949). This system receives inputs from all sensors, and acts in turn on both the cerebral cortex and the endocrine system, in particular the pituitary-adrenal system. In turn, there is a feedback of the latter systems on the reticular formation, so that arousal is really a neuroendocrine process (Hennessy and Levine, 1979). Moreover the action of the reticular formation is nonspecific: it does not "say" 'Look at that' or 'Smell this', but just 'Watch out: something is up'. It prepares the higher centers of the brain to process the output of the sensors, or keeps them generating new information.

Exploratory behavior may be elicited by environmental events or by internal events, particularly in the brain. In either case exploratory behavior is driven by curiosity, which may be regarded as the drive generated by a knowledge deficit or imbalance. Thus a problem may be construed as the difference between what is known and what one wishes or needs to know.

Animals do not always wait for stimulation to trigger exploratory behavior: all of the higher vertebrates actively seek stimuli of certain kinds, so that stimulation comes sometimes as a result of behavior, not the other way round. (They seek excitation up to a certain point, avoiding it only when it becomes excessive. Roughly speaking, the value of the overall external stimulation is bell shaped, but the maximum shifts with the internal state: to lower excitation values when the organism is tired or sick, to higher excitation values when it is healthy. (See Leuba, 1955.))

The schema of active exploratory behavior is not *stimulus–new internal state–response* but rather *curiosity–exploratory behavior–stimulus–new internal state-response* (Berlyne, 1954). Moreover, as exploration proceeds curiosity may be satisfied—i.e. the epistemic drive reduced. Or, on the contrary, the discovery or invention of new items may augment curiosity and thus sustain exploration or redirect it. Thus, whereas most other behavior types tend to reduce the corresponding drive, exploration may increase it. That is, inquiry is often self-sustained: it keeps generating problems. We call this type of inquiry *research*, to distinguish it from mere *fact-finding*, a process that reduces the epistemic drive as the corresponding problem is solved.

Looking for an address and computing a value of a function are instances of fact-finding inquiry. On the other hand conceiving of a model of the problem-solving process, and designing an experiment to test it, are examples of research. A fact-finding process comes to an end when a solution is found or shown to be impossible with the means at hand. In contrast, research generates new problems as it proceeds: in principle it is open-ended either because the solutions are imperfect or because they allow one to pose further problems. Most computer programs are of the fact finding type and a few of the research kind, but none is designed to pose new problems. Computers are problem solving aids, not problem finders.

A problem is a knowledge gap, and a problem solving process is one aiming at filling such gap: it has a very definite purpose. If we knew more about the neurophysiology of questioning and learning we would be able to picture this process with some precision, as the trajectory of a point in a cognitive space, from formulation to solution. See Figure 7.1. The starting point is included in the region of the cognitive space constituted by all the items relevant to the formulation of the problem—i.e. what may be called the *problem setting* or *framework*. Unfortunately, we do not even know which variables to take as axes for building such cognitive spaces.

Presumably the cognitive space of a newborn is very small, exclusively sensory-motor, and nearly amorphous. As the child grows up and learns,

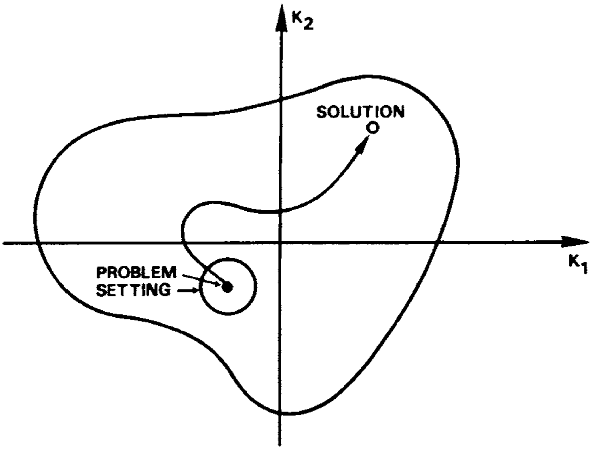


Fig. 7.1. Cognitive state space, and problem solving as trajectory of point representing state of knowledge, from formulation to solution. The axes K_1 and K_2 are (ranges of) functions representing neurophysiological variables characterizing the particular neural system performing the cognitive task in question. The cognitive states in the neighborhood of the problem constitute the problem setting, i.e. the collection of knowledge items relevant to the formulation of the problem.

its cognitive space expands qualitatively (new axes) as well as quantitatively (wider regions), and it becomes structured—i.e. the various knowledge items get interrelated forming systems. Such systems act as frameworks or settings for new problems. Thus when confronted with a new problem we are not always at a loss, but can often place the problem in our cognitive space and reconnoitre its neighborhood (setting) in search for clues. To change the metaphor, the inquirer forms, stores and organizes "frames" or data structures representing stereotyped situations, like moving about in a school building; such frames and frame systems are ready to receive or generate new experiences (Minsky, 1977).

All hard problems demand dedication, often over very long periods. However, it is common experience that continued exclusive concentration on a single problem does not pay: one is likely to fall into a rut that may lead to a *cul de sac*. Distractions are useful at this point: either turning temporarily to lighter problems, or just going for a walk. This manoeuvre has sometimes been interpreted as shoving the problem under consciousness and letting the Unconscious do the work. However, the recourse to the inscrutable Unconscious is not only a refuge in ignorance but also quite unnecessary, for there is a better explanation.

Concentration on a single problem tends to strengthen certain neural pathways while inhibiting others. (Recall Ch. 1, Section 1.1.) Distraction loosens some connections and gives others a chance to be established. This allows us to get off the trodden path and explore alternatives. When not under the pressure to move along the rut one may wander more freely in the cognitive space, which may eventually lead to the desired solution. Such happy end would not occur if we had no definite problem in hand (or rather brain) and some competence to handle (or rather mind) it. Neither the Unconscious nor blind chance (pervasive though it is), but just the leisurely exploration of new possibilities, does the trick.

In general, repeated experiences facilitate the formation of routines and *eo ipso* impair the ability to solve and even "see" problems of new kinds. Again, the use-disuse hypothesis explains this phenomenon: the neuronal connections become stronger, the more they are exercised. Hence experience, when confined to a few kinds, tends to decrease plasticity, whereas it tends to enhance it when varied. When a routine develops the tendency to disregard problems of new kinds, or to "assimilate" them to those of old kinds, it becomes an obstacle. One tries his old tricks on the new problems and, more often than not, one fails. This phenomenon of crystallization is what the Gestalt psychologists used to call *Einstellung* (problem solving *set*), and Duncker (1945) *functional fixedness*. (Cf. Katona, 1939; Birch and Rabinowitz, 1951.) People with fixed tasks become more and more rigid in their ways, until they become capable only of reproductive not productive thinking (Wertheimer, 1961). *Moral*: When scouting for someone capable of facing a tough new problem do not advertise for an experienced specialist but for a newcomer willing to take the risk and jump over disciplinary frontiers. He may undergo the neural reorganization we experience as the flash of insight (or *aha* experience).

By themselves, then, learning and praxis do not improve questioning ability or problem solving competence. The effect of both depends largely on the inquirer's attitude and opportunities. If his goal is to maximize his knowledge store or his practical utility, he will absorb solutions more readily than generate problems. On the other hand, if his goal is to maximize his contribution to knowledge, he will prefer unsolved problems, whether ambitious or modest. However, even the research-oriented inquirer—the one who hops from problem to problem instead of accumulating solutions—faces at all times the danger of becoming an erudite. Indeed, as science, technology and the humanities advance, it is only natural, as well as reasonable, to resort to the stock of solved problems when first confronted with a new problem. This tactic is bound to succeed if the new problem is indeed similar to an older solved problem. But if the problem bears only a superficial analogy to an older solved problem, the erudite's procedure will lead nowhere or, worse, it will yield a wrong solution, or will generate more useless problems than it solves. (Adams (1980) calls this the 'hit-and-run' approach.)

The questioning ability, the capacity to "detect" new problems, can be trained or inhibited. The training can be of either the argumentative or the investigative type. The former consists in encouraging questioning and arguing without engaging in any inquiry beyond some fact finding—usually the spotting of the proper chapter and verse. This is the training that theology students, and even many humanities students, receive in the hope of discovering the truth by exegesis of canonical texts and by argument. As we have seen (Ch. 6, Section 3.1) it serves the entrenchment of dogma rather than the generation of new knowledge. The best training of the problem finding and solving capacity is one in mathematics, science, or technology. Indeed in these fields original work consists in investigating open problems with the aim of coming up with new results. Not that criticism is absent from such training, but it is only one among several means for producing or at least controlling new knowledge.

The questioning ability can be inhibited by repeatedly declining to answer the child's natural questioning, by giving unintelligible or false answers, or by imposing the uncritical acceptance of what is regarded as the right view. Unfortunately too many schools all over the world discourage questioning: they are *dressage* schools aiming at the training of conformists. (As cosmologist Hermann Bondi has stated, the few failures to this training in question-stopping are called 'scientists'.) There are three obvious reasons for this kind of schooling. One is that a questioning child is a source of additional work or even trouble. Another is the belief that all a child must learn are "facts" (data) and skills—questioning not being among the latter. A third is that questioning can be worse than annoying: it can be subversive, and most of the people who wield power do not want society to change (Ackoff, 1978, pp. 4–5). As a South American minidictator said, there is but one step from the scientific finding that matter is unstable, to the suspicion that even the most sacred institutions could be unstable as well.

Because of the obsession for results or findings, the problem of the psychological mechanism of the emergence of problems has hardly been studied. All we seem to know is that inquisitiveness is innate in many species and that it has a positive survival value. On the other hand there are a few hypotheses about the problem solving process. The oldest is perhaps that problem solving proceeds by association. Although this view may explain (in a superficial way) why some ideas are recalled at the proper time, "it cannot explain the appearance of other ideas, e.g., original ideas" (Meier, 1931).

Most of the workers in this field are either empiricists or cognitivists. The former hold that, when tackling a problem, the animal proceeds by trial and error and gropes gradually towards the solution, i.e. reaches it through decreasing errors. This is at best a description of problem solving behavior. It does not explain the process because it does not tell us how the tentative solutions (hypotheses) are formed or why the process should converge. (A genuinely haphazard trial and error process should hit on the solution only by accident: there should be no gradual diminishing of discrepancies.) On the other hand cognitivism claims that the animal starts out its exploration with a whole set of hypotheses in mind, or else hits on the correct one in a flash of insight.

There may be something in each of the above rival views, and undoubtedly both of them miss something. The animal's behavior in the face of a new problem depends on its experience in handling problems of a similar kind, as well as on its goals and expectations. If it has no experience whatever, it will either avoid the problem altogether or tend to proceed by trial and error until reaching a satisfactory solution or giving up in fatigue or boredom. If on the other hand the animal does have some experience with similar problems, it will start out with a fund of guesses and try them out in succession. In either case, though, the subject keeps forming and testing new guesses. Moreover the process is not totally haphazard because there is feedback from some outcomes. I.e., unless the proposed solutions are totally irrelevant, or their adequacy kept from the subject, he may learn from his mistakes—not only learn to give up some of the wrong answers but also in what direction he should advance toward the correct response.

There is no finding and solving of problems without some motivation, but there are many kinds of motivation. Even in the case of purely cognitive problems, such as those in mathematics, basic science, and the humanities, the individual researcher may be driven not only by curiosity but also by love or hatred, celebrity or power, security or money. (My own motivation in writing my best physics paper was political.) So much so that, when any such noncognitive goal is reached, the individual may no longer feel motivated to pursue his research. (Most research careers terminate in a doctorate, a professorship, or a deanship.) Yet no extracognitive drive, however strong, will accomplish anything of cognitive value unless accompanied by strong curiosity helped by talent, imagination, and industry.

Nor is a strong epistemic drive, allied to competence, sufficient to succeed in problem solving activities. Three further factors are involved: aiming at certain collective goals, choosing the right problem, and luck in investigating the problem at the right time in the right inquiring community. The collective goals are those of the given field of inquiry: they are not impersonal but are in the intersection of all the sets of individual motivations of the workers in the given field. Thus the collective goal of mathematics and basic science is the *finding of patterns*; that of technology, the *designing of useful artifacts*; that of the humanities, the *understanding of culture*; that of the liberal professions, *serving needs* of others. No matter how selfish a worker in any of these fields may be, he must aim at one of those collective goals if he is to make any contribution to it. So much for the collective goals of inquiry. As for choosing the right problem at the right time in the right circumstances, this matter deserves a separate section.

1.2. *Sources and Choices*

The traditionalist approach to learning presupposes that basic (or perhaps all of) human knowledge is locked in certain texts, whether sacred or secular. This is the approach adopted by religionists, schoolmen, hermeneutic philosophers, and doctrinaire ideologues. It follows that learning consists in studying and suitably "interpreting" such texts, and trying to solve every new problem by "applying" the suitable passages. (Failure in solving problems is blamed on the "interpreter" not on the texts.) In short, in this approach there can be no genuine new knowledge, and this because no new problems are admitted.

Modern workers in mathematics, basic science, applied science, technology, and the advanced sectors of the humanities, make no such presupposition and therefore proceed in a radically different manner. They presuppose, on the contrary, that nobody knows everything, that much of what little we know becomes quickly obsolescent, that our natural and social environments keep posing new challenges to be conceptualized as problems to be investigated, and that certain inquiries consist in posing and solving problems with no immediate practical roots or implications. In short, research-oriented inquirers know that *inquiry consists in investigat-*

ing problems. And they know that there are two problem sources: *external*, or originating in the natural or social environment, and *internal*, or originating in our own fund of knowledge—or rather in its gaps.

Talk of problem sources should be taken metaphorically not literally, for problems do not spring before us the way water springs from an artesian well. We do not discover problems the way we discover iron ore deposits: problems, like their solutions and, in general, all conceptual objects, are *made* by us. To be sure, not all environmental challenges arise spontaneously: some result from mismanagement of natural or social resources. However, man has lived for many millennia without transforming such challenges into those peculiar neural processes we call 'problems'. External challenges are occasions or opportunities, not causes of inquiry. Unless there are well equipped, trained and motivated brains, no challenge, however pressing, will elicit the conception of the corresponding problem, let alone of a research project to investigate it. Thus even now most people do not realize the gravity and urgency of the challenges to the very survival of the human species—starting with the arms race—so they keep postponing facing them, i.e. transforming them into problems to be investigated and solved.

So, it is simply not true that the environment, in particular society, exudes problems: individual brains, immersed in a suitable culture, create them. Nor is it true that every single problem we do manage to pose and solve is nothing but a response to challenges posed by "the historical development of productive forces and production relationships", as an early advocate of sociologism put it (Hessen, 1931, p. 203). Most problems in logic, pure mathematics, physics, astronomy, anthropology, history, and philosophy—to mention but a few fields of inquiry—are internal, not external. Workers in these fields handle mostly problems originating in what used to be called 'idle curiosity'—a sin to be shunned by every properly educated child. Let us praise and promote idle curiosity, for it prompts the most noble and, in the end, also the most useful of activities: inquiry. As Nobel laureate George Wald said, "The great questions are those an intelligent child asks and, getting no answers, stops asking. That is known as growing up." (Quoted by Teuber, 1966, p. 583).

Obviously, there is an enormous variety of internal problems as well as a number of kinds of stimuli and inhibitors to the problem finding activity. See Table 7.1.

Having emphasized that many problems in basic research originate in disinterested (idle) curiosity, let me hasten to acknowledge that others are

TABLE 7.1
Some stimulants and inhibitors of problem finding and solving

Stimulants	*Inhibitors*
Exploring new territory	Censorship (by schools or ideologies)
New facts to be checked or explained	Routine
Anomalies or contradictions	Complacency
Moderate criticism	Destructive criticism or indifference
Moderate competition	Rat race
Group cooperation	Infighting
Social rewards	Absence of social rewards

offshoots of practical problems, or have solutions that can be used to solve practical problems, whereas still others are elicited by environmental situations. An example of the first kind is the wealth of mathematical and scientific problems posed by technological developments; thus hydrodynamics owes more to aeronautics than the other way round. An example of the second kind is the utilization of biology in medical research and practice. An example of the third kind is social science: here the choice of problems is largely motivated by contemporary events. Let us take a look at this point.

Coleman (1980) has shown how the Chicago school of sociology, which flourished in the first quarter of this century around Robert Park, was mainly interested in the problems associated with the urbanization of North America (slums, ghettos, gangs, prostitution, etc.). Likewise the Columbia school built around Paul Lazarsfeld tackled some of the problems that arose in the 1930s, mainly the formation of a national market and of a national communication network. These problems called for a methodological shift, from the study of small groups (e.g. urban subcultures), to samples of large regions, sometimes national samples. Finally, the third or contemporary phase appeared with the beginning of social policies (as distinct from economic policies) in health, education, welfare, employment, etc., in the late 1960s. This research into social policies involved process evaluation, product evaluation, and even some large scale social experiments. It is definitely a shift towards applied social science. (Interestingly enough its leader, Professor Coleman, started out as a mathematical sociologist.)

So, there is two-way traffic between the internal and the external sources of problems. Besides, like every other human endeavor, problem finding and solving are subject to chance. Sometimes chance events spark off problems or solutions, at other times they nip in the bud problem solving processes. A book on probability, seen by chance by a meteorologist, gives him the idea of investigating random processes in the atmosphere. A film on alcoholics gives a neurophysiologist the idea of pursuing a certain clue regarding taste formation and aversion. A chance encounter between a mathematician and a psychologist suggests to the former a new problem and to the latter a solution to his current problem. Computers are protected against such chance encounters: they are always programmed. So, they are neither led to truth nor misled into error in a haphazard way. Human brains, on the other hand, are biased cognitive roulettes.

The bias lies usually in the curiosity of the researcher or in the urgency of the problem. But sometimes fashion is involved; some problems are fashionable even when unimportant, whereas others are unfashionable even when important. One cause is obvious though unjustifiable: most middle class people like to be thought of as gentlemen or ladies of fashion. (Nowadays it is unfashionable to say that Bach and Wittgenstein are boring, that psychoanalysis and much of cosmology are unscientific, or that the abuse of computers is a threat to science.) Another cause is less obvious and thoroughly justified: science and technology must be up to date and, justifiably, this draws many people to work on recently posed problems.

Finally there is the question of timing. The alchemists posed too soon the question of the transmutation of metals, and the monetarists are too late in advocating a return to the competitive (free) market as the solution to the problems of the advanced capitalist economies. As Nobel laureate Sir John Kendrew said, "One has to ask the right question at the right time". But what is a right question? And can we say beforehand whether a question is good or bad, or must we wait and see what impact research on it has had? Let us deal with one question at a time.

Clearly, not all problems are worth the same. Thus finding out the neural mechanism of problem formation has a far greater cognitive importance than discovering a huge new deposit of mineral oil, but the practical importance of the latter may be far greater than that of the former. So, when ranking problems (or anything else) we should start by specifying the respect in which we are doing it: cognitive or practical. And we should keep in mind that such categorization may be only temporary, for some problems that start out being "academic" may turn out to be practically important (such as the problem of nuclear forces), whereas some practical problems (such as whether or not trenches for warfare should be straight) may disappear before being solved.

Once this has been done, how shall we assess the relative importance of problems in the given respect? Will difficulty be a suitable measure, or perhaps the length of time that the problem has been around? The former is not a good measure, for difficulty is largely subjective: some good mathematicians experience considerable difficulty in performing elementary sums, whereas computers can perform calculations beyond the reach of any brain. Nor is length of time—particularly when measured by the number of pipes smoked by Sherlock Holmes—a good indicator of problem importance. Thus the four-color problem was solved only recently after two centuries of unsuccessful trials, but it is neither theoretically nor practically important: it is a stray problem and presumably its solution will not elicit a spate of other mathematical problems. We must look for alternative criteria.

We may start by classing problems into good and bad according to this definition: A problem is a *good* problem if (*a*) its solution would make some contribution to knowledge or human welfare and (*b*) it can be solved with existing or conceivable means. But of course not all good problems are important: some are trivial, others mediocre, and a few exceptional. We stipulate that a good problem is *important* if (*a*) it belongs to a problem system (rather than being stray), (*b*) it is deep, i.e. presuppose or is likely to upset basic principles or traditional behaviour patterns, and (*c*) its solution is likely to make it possible for a number of other people to pose further good problems.

By using the above definitions we can estimate a priori the value of problems. However, here as elsewhere our estimates may be erroneous. In any case three things are clear. One is that all research proposals are evaluated both a priori and a posteriori, and prior evaluation rests on some more or less tacit idea of problem worth. Second, if these ideas of problem worth were rendered explicit and discussed in the open, project evaluation would be more rational and objective, and therefore more fair. Third, very few researchers have a knack for "spotting" important problems, even fewer the ability and drive needed to solve them. Most researchers are better at problem solving than at problem having. (Worse, many researchers do not even seem to know that research consists in working on problems—so much so that, when writing their final reports, they seldom start by stating their problem.) Only exceptional investigators, such as Newton and Hilbert, are capable of drawing lists of important problems nourishing several generations of workers. This requires flair as well as experience. (Cf. Bunge, 1962.)

Estimating the worth of problems with hindsight is easier than doing it a priori, but there are pitfalls here too. First, historians know that it is easy, perhaps unavoidable, to write "whig history"—i.e. to view the past against the background of our own problems and aspirations, and so to overrate certain accomplishments of our predecessors (mainly those which we have used) and underrate others. Second, even an objective indicator of worth, such as the volume of publications devoted to a problem, is not completely reliable, for there are always extrinsic factors, such as fashion, ideology, and availability of resources. Moreover in certain fields, such as philosophy, the relation between the importance of a problem and the volume of the publications devoted to it is inverse, not direct. Thus in recent philosophy trivial problems, such as the status of counterfactuals, the raven paradox, and the way to identify individuals across (logically) possible worlds, have attracted far more attention than the concepts of problem, partial truth, or attribute.

Although there are no rules for generating good problems, it is possible to give some helpful advice in this matter. First, *reexamine old problems*, for some of them may have changed just because their setting has altered, so that they can now be restated and solved in a different way. For example, the entire problem system of genetics was altered by the emergence of molecular biology and, in particular, the discovery that DNA is the genetic material. Also, practical problems "do not stay solved" (Ackoff, 1974) because society changes. Thus the automobile solved the urban transportation problem at the beginning of our century but is no longer practical.

Second, *examine critically* the known solutions to old problems, for there must be some flaws in some of them. (Enrique Gaviola, personal communication.) For example, by repeating a run of measurements or calculations, or reanalyzing a set of assumptions, one is bound to find something to correct or improve, generalize or discard. Thus we still do not have a satisfactory derivation of thermodynamics from statistical mechanics, or a good theory of liquids.

Third, *apply known methods or theories* to new problems, and check whether they still hold. If they do, you will have extended the domain of those methods or theories, and if they do not you may have generated a whole new problem system. For example, the Newtonian theory of gravitation, originally devised to explain the solar system, was successfully extended beyond it—until its own limits were discovered.

Fourth, *generalize* old problems: try introducing further variables or more complicated relationships among them. For example, introduce nonlinearities or inhomogeneities in equations, or impurities or external perturbations in concrete systems.

Fifth, *dig deeper*: try to obtain known results from assumptions concerning deeper levels. For example, try to explain psychological laws in neurophysiological terms, or historical trends in terms of social and economic laws.

Sixth, *look outside*: search for relationships to problems belonging to different fields. For example, explain chemical reactions as nonelastic scatterings of the reactants, or relate economic activities to political and cultural ones.

Seventh, *go out of fashion*: choose tough and interesting open problems that are not being currently investigated by others.

If all of these recipes fail, keep searching the literature, consult with others, ask someone for a problem, or take a holiday. Should all these moves fail after a couple of attempts, give up: this is far better than simulating research when actually doing nothing but keeping busy with books, instruments or computers.

An experienced and productive investigator needs no advice on how to generate new problems, for he stumbles on them all the time, and he may be in a position to give such advice. Problems seem to arise spontaneously in the course of his research, and to do so beyond his control and often to his own surprise. Sometimes the new problems are so numerous that he has to farm them out to assistants or students. For example, in measuring a magnitude a scientist may discover a fault in the experimental design or its implementation, which flaw generates the problem of overcoming it. In the course of the investigation of this problem he may hit on a new effect or a new technique, and so he may get sidetracked: the derivative problem may prove to be more pressing or even more interesting than the original one. Or in building a mathematical model of some thing or process, a scientist or technologist may formulate a new equation posing a new mathematical problem; conversely, in studying some mathematical work the idea may occur to him of trying the newly learned mathematics on one of his substantive problems that had proved to be intractable before. In sum, original research, unlike routine research, is an *open ended and self-sustained process.* If and when it does grind to a halt it is because people have lost their curiosity or the freedom to satisfy it.

2. FROM INTUITION TO METHOD

2.1. *Intuition*

When faced with a problem of a familiar kind we resort to our own fund of knowledge, or to the knowledge stored in other people's brains or in libraries. This will not suffice if the problem is of a new kind: in this case we need additional knowledge and some intuition or flair to guide us in the search for such knowledge. Intuition or insight is of course that proteic and ill defined ability to spot problems or errors, to "perceive" relations or similarities, to form concepts or hypotheses, to conceive of strategies or tactics, to design experiments or artifacts—in short to imagine, conceive, reason or act in novel ways. (Cf. Bunge, 1962.)

The novelty occurring in a flash of insight is of either of the following kinds: *radical* (unprecedented) or *combinatorial* (the result of combining previously known items). Radical novelty in ideation consists presumably in the formation of a psychon (plastic neuronal system) of a new kind, whether spontaneously or under the influence of the activity of some other psychons. On the other hand combinatorial novelty in ideation, i.e. association, consists presumably in the linking of two or more activities in so many neuronal assemblies (Hebb, 1949, p. 134). As long as the latter remain isolated from one another, the two ideas stay apart. But if, perhaps by chance, a bridge is formed between them, then the relation between the two formerly separate ideas emerges suddenly as a third idea. In both cases chance, as well as the deliberate scanning of a region of the cognitive space, are likely to occur.

The newborn has no insight: he must build it up. However, sheer quantity and variety of experience are not sufficient to acquire a powerful intellectual intuition although they are necessary for it (Birch, 1945). Hard work of the right kind, success, and luck—i.e. suitable circumstances—are needed as well. Hard work of the right kind—tough tasks with scant means—is necessary for it cannot be performed in a routine fashion but calls for imagination. Success is needed because repeated failure discourages and counsels turning to easier tasks. And luck is needed because adverse circumstances beyond our control may prevent us from honing our wits. Thus too long hours applying rules of some kind, or making routine calculations or measurements, will blunt one's intuition. On the other hand repeated exposure to varied problems requiring more ingenuity than specialized knowledge will hone it. For this reason Dreistadt (1969)

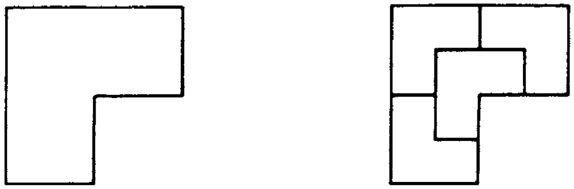

Fig. 7.2. The Farm Problem: divide the L shaped lot into 4 parts with the same shape and size.

recommends proposing problems such as the Farm Problem to cultivate problem solving skills. See Figure 7.2.

No problem can be understood and handled successfully without some intuition or "vision" of it as a whole and against its setting. This holds for all problems, whether cognitive or practical, in every field of human endeavor, from science to technology, from art to the humanities, from management to politics. However, the need for intuition in every field of human endeavor does not entail that is suffices, or that we cannot go beyond it, or that it is superior to experience and reason.

Intuition is insufficient: it is not a substitute for work but a guide to it. There is no substitute for hard work except of course soft work—but this one does not really work. The so-called "aha experience" (or "eureka phenomenon") does not come out of the blue but after hard thinking or doing, after trying different hypotheses or methods, and repeatedly reorganizing one's ideas. (Cf. Gruber, 1981.) Divination is no short cut either: it is no substitute for exploration in the light of specialized knowledge. For example, the rate of success of dowsers (water witches) is far inferior to that of geologists and water engineers: "We know of no other hypotheses that have been put forth so persistently over such a long span of years with such surprisingly negative experimental findings as the hypothesis that water witching 'works'" (Vogt and Hyman, 1959, p. 82; see also Randi, 1979).

Intuition is preliminary and tentative rather than final: it must be elaborated and checked. Moreover mathematics, science, technology and philosophy keep introducing counterintuitive or implausible concepts, theories, and methods. (Actually every radically new idea, even if initiated intuitively by its creator, is likely to sound counterintuitive to all others.) In short, intuition is indispensable but intuitionism, the epistemological doctrine according to which it is sufficient, is false. (For a criticism of philosophical intuitionism see Bunge, 1962.)

Counterintuitive ideas are particularly conspicuous in contemporary science and technology. This is so because appearance is only skin deep, and reality so complex that it can be grasped and controlled only with the help of very sophisticated instruments. Photons are not tiny particles, solid bodies are not continuous, organisms are not machines, and national economies are not households. Actually we need not go far out into modern science and technology to find problems and solutions that defy intuition. Recall the story of the king who promised to reward one of his subjects with a few grains of wheat: one for the first square of the chess board, two for the second, four for the third, eight for the fourth, and so on. He had not realized that the total number of grains promised was $2^{64}-1$, which is more than the annual world wheat crop.

As long as we stay on an intuitive level we are constrained to proceed by guessing, also known as the trial and error "method"—actually the very antithesis of a method. To be sure, this procedure is bound to succeed sooner or later in the case of problems involving a manageable number of alternatives. Thus Edison and his coworkers hit on the right material for manufacturing light bulb filaments only after having tried haphazardly nearly 10,000 different materials—practically all those known in his time. (He could have proceeded methodically if solid state physics had existed in his time.) But the hit-or-miss procedure is unlikely to succeed with complex problems even after repeated trials. Electrodynamics and the dynamo were not outcomes of blind trials but of hard and sustained theoretical and experimental work. The alchemists tried for thousands of years to turn lead and other "base" metals into gold by combining and treating at random a number of substances. Nothing of the sort could possibly have worked: a wholly different approach was needed to solve that problem. We shall elucidate the obscure and important notion of an approach in Section 3.2 after having examined the concept of a method.

2.2. *Method*

We are all familiar with a number of methods, or regular procedures for handling problems of restricted kinds, in all sectors or human endeavor, from mathematics to butchery. For example, neuroscientists use the Golgi staining technique, in conjunction with microscopy, to render individual neurons visible. They also employ microelectrodes to record the electrical activity of single neurons, and electroencephalography to record the activity of entire regions of the brain. All these are *techniques*, or special methods. Every technique has a restricted scope, i.e. it cannot be exported to distant fields of research.

Philosophers have been acquained since Antiquity with three conceptual methods: Socrates' maieutic method, Porphiry's tree questioning, and the method of hypothesis. (We do not rate contemplation as a method, for there are no rules for contemplating in a productive way.) The maieutic method supposedly consists in extracting knowledge, by clever questioning, from the student's inborn storehouse of knowledge. Actually the teacher must know the answer and must know how to supply clues that will allow the student to exploit his own background knowledge. The method works for purely logical problems but does not help solve problems in, say, statistics, biochemistry, or history. Tree questioning consists in surveying the set of possibilities and dividing it step by step into mutually disjoint subsets until the wanted subset is reached. It works whenever the subject is initially given a finite set of possibilities and has the means to eliminate the wrong ones—which is not often the case in original scientific or technological research. Finally, the method of hypothesis, or hypothetico-deductive method, consists in the sequence *invention* (of idea or device)—*trial*—*evaluation*. This method is used in all cognitive fields, including ordinary knowledge. And it is used systematically in mathematics, science, modern technology, and philosophy, where hypothetico-deductive systems (theories) are plentiful. See Figure 7.3.

Not all techniques are alike in accuracy, foundation (or justification), and cost. For example, to detect defects in the hull of a ship, X-rays and ultrasound are more accurate and better founded than banging with a hammer—but they are also more expensive. Again, forecasting the state of the economy by divination or on the basis of some economic ideology is inferior to extrapolating recent trends; and forecasting on the strength of well-confirmed theories and hard data should be superior to trend extrapolation.

A technique or special method may be called *scientific* if (*a*) it is intersubjective in the sense that it gives roughly the same results for all competent users, (*b*) it can be checked or controlled by alternative methods, and (*c*) there are well-confirmed hypotheses or theories that help explain, at least in outline, how it works. A method that complies with only one or two of these conditions may be called *semiscientific*, and one that complies with neither *nonscientific*. Note that, whereas condition (*b*) is that of testability (checkability), clause (*c*) is that of foundation or justification, as opposed to faith or authority.

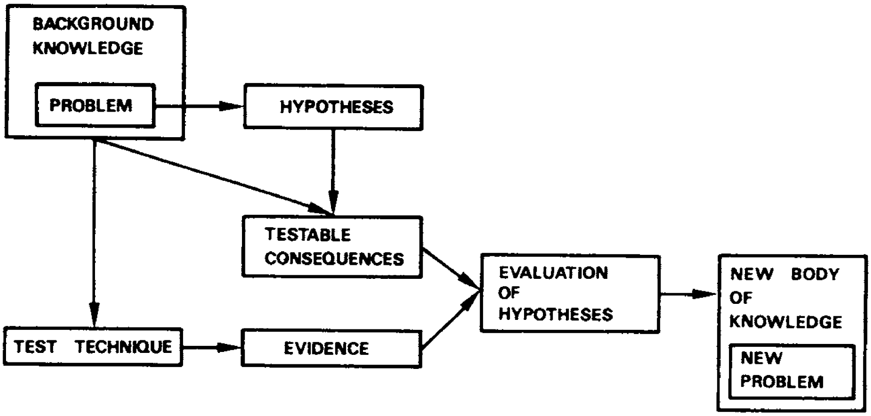

Fig. 7.3. A scientific research cycle. The importance of a scientific research is gauged by the changes it induces in our background knowledge or by the new problems it poses. Adapted from Bunge (1967a).

For example, whereas random sampling is scientific, the ink-blot test is not. Indeed the former is objective, can be checked by investigating the whole population, and is founded on the probability calculus. On the other hand the ink-blot test is subjective and mysterious. A good example of a semiscientific technique is the memorization of nonsense syllables, widely used to study verbal learning. It is objective and can be checked by alternative techniques, but it rests on a false hypothesis. The hypothesis is that, by memorizing nonsense syllables such as *giz* and *toc*, the "blank slate" condition is reproduced, so that learning does not depend on previous knowledge. But this is false: in order to memorize such syllables the subject is likely to associate them with familiar words or images—e.g. 'giz' with 'gizmo' and 'toc' with 'woodpecker'. There is no pure verbal learning. Like all learning, verbal learning is rooted in previous knowledge: it is a growth process, not one of haphazard piling up of unrelated items.

The inception of a new technique may revolutionize a field of human endeavor or it may even give rise to a new field. Think of triangulation, printing, the microscope, chromatography, or computers. The design of a new technique is, increasingly, the work of a sequence or of a team of specialists composed of scientists, technologists, and craftsmen. Much effort is being devoted in science and technology to the invention, improvement, and adaptation of new techniques. However, it should never be forgotten that techniques are means not ends: means for knowing things or getting things done. The goal is either a bit of knowledge or a commodity.

The learning of techniques is an important part of the training of experts. It is also the easiest part, for one need not know why or even how the technique works in order to use it competently. (For example, nobody seems to know how the Golgi staining technique works.) Therefore most specialists are skilled technicians: performers rather than musicians, color mixers and dabblers rather than painters, microscopists rather than cellular biologists, electrode pushers and recorders rather than neuroscientists, calculators rather than mathematicians, and so on.

When on their own, technicians are likely to engage in routine work, haphazard tinkering, or even wasteful activity. Technicians perform best when they are components of teams led by productive artists, technologists, scientists, or managers. This is so because in such case their work services a long-range goal and receives the feedback necessary for correcting false moves. As a component of such a team a technician's tinkering may lead on to a new technique or to the discovery of a previously unknown category of facts.

Some techniques born with a narrow scope have evolved eventually into general methods. Microscopy, the method of successive approximations by iteration, and even the scientific method are cases in point. Indeed microscopy is now being used not only in biology, where it was first applied, but also in physics and various branches of engineering (e.g. metallurgy), as well as in some branches of the humanities (e.g. art history). The method of successive approximations by iteration is employed in all of applied mathematics and is a paragon of scientific procedure. One starts by computing or guessing a first approximation. This approximate solution is then fed back into the original problem to yield a second solution, and so forth. In this way more and more accurate solutions are obtained: the solution is the limit of the sequence. Every partial solution is built upon the preceding ones, and the increase in accuracy or degree of truth is uniform. That is, the iterative procedure is constructive and convergent.

We mentioned the scientific method as one with a large scope, in contrast with any of the special methods or techniques. What is it? Opinion varies from radical skepticism, which denies its existence, to dogmatism, which believes it to be a set of simple, invariable and infallible recipes for finding definitive truths. We take the *scientific method* to be the following ordered sequence of cognitive operations:

1. *Identify a problem* (whether gap or indentation) in some body of

knowledge—if possible an important bit of ignorance. If the problem is not stated clearly, go to the next step, otherwise to the subsequent one.

2. *State the problem clearly*, if possible in mathematical terms or in terms of measurement operations.

3. *Search for information, methods or instruments* likely to be relevant to the problem—e.g. empirical data, theories, methods of measurement or computation, measuring instruments, etc. I.e. scan what is known to see whether it can help solve the problem.

4. *Try to solve the problem with the help of the means collected in the previous step.* Should this attempt fail, go to the next step; if not, to the subsequent one.

5. *Invent new ideas* (hypotheses, theories, or techniques), *produce new empirical data*, or *design new artifacts* that promise to solve the problem.

6. *Obtain a solution* (exact or approximate) of the problem with the help of the available conceptual or material means.

7. *Derive the consequences* of the solution thus obtained. If the solution candidate is a hypothesis or a theory, compute predictions; if new data, examine the effect they may have on existing ideas; if new artifacts, assess their possible uses and misuses.

8. *Check the solution.* If the solution candidate is a hypothesis or a theory, see how its predictions fare; if new data, try to replicate them using alternative means; if new techniques or new artifacts, see how they work in practice. If the outcome is unsatisfactory, go to the next step, otherwise to the subsequent one.

9. *Correct* the defective solution by going over the entire procedure or using alternative assumptions or methods.

10. *Examine the impact* of the solution on the body of antecedent knowledge and state some of the new problems it gives rise to.

Table 7.2 exhibits schematically the scientific treatment of three typical problem types: one theoretical, one experimental, and a third one technological.

The scientific method has some points in common with the method of successive approximations by iteration. First, scientific research proceeds *gradually*: even the correct insights that may be hit upon by chance, and revolutionary new ideas, are the outcome of previous work, as well as subject to correction. Second, scientific research yields, at least with reference to the world of facts, *partial truths* rather than complete and accordingly final truths. Third, the scientific method, in contrast to the hit-or-miss procedure of common sense and unbridled speculation, is *self-*

TABLE 7.2
Three typical problem types.

Step	*Empirical problem: measure*	*Theoretical problem: explain*	*Technological problem: design*
1	What is the value of X?	Why does X have the value x?	How can X be done?
2	What is the measured value of X to within error e?	What premises entail that X is worth x?	How can we design a Y capable of doing X with maximal efficiency?
3	What experimental arrangement(s) Y allow to measure X with error less than e?	What theories Y, subsidiary hypotheses h, and data d imply that the value of X is x?	What information can help design Y?
4	Perform measurement of X with means Y. If Y proves inadequate go over to step 5, otherwise to 6.	Compute the value of X with the help of Y, h and d. If the result is implausible go to step 5, otherwise to 6.	Design Y with the help of the information gathered in previous step. Should design prove inadequate go to 6.
5	Try new technique Y'.	Try new theory Y', or new subsidiary hypotheses h', or new data d'.	Try new design.
6	Use Y' to measure X.	Compute the value of X with Y', etc.	Build an artifact (or a scale model) Y' or run a computer simulation based on the design.
7	What does the outcome of 6 imply or suggest?		
8	Measure X with alternative techniques. If the new result is implausible go to step 9, otherwise to 10.	Compute X with alternative assumptions or methods. If the new result is unsatisfactory go to step 9, otherwise to 10.	Put Y' to some uses and misuses. If Y' does not work satisfactorily go to step 9, otherwise to step 10.
9	Look for systematic errors and correct them.	Look for possible sources of error and correct them.	Look for flaws in design and correct them.
10	How does the new result affect knowledge or practice, and what new problems if any does it pose?		

BACKGROUND
KNOWLEDGE
PROBLEMS
METHOD
SOLUTIONS

Fig. 7.4. A method as an input-output box. Input: problems and background knowledge; output: solutions.

correcting: it can help recognize errors and obtain higher order approximations, i.e. truer answers. One difference between the scientific method and the mathematical iterative procedures is that the former never allows one to find exact solutions of nontrivial problems. Another difference is that the scientific method can be applied to all inquiries, whether mathematical or empirical, scientific, technological, or humanistic. (Some philosophers deny this: we shall come back to this point in Section 3.2 and in Vol. 6.)

Every method, regardless of its scope, can be construed as a device transforming problems, together with the data relevant to them, into solutions. See Figure 7.4. In this context we understand by 'data' not only the givens of the problem but also all the components of the body of relevant available knowledge, including ontological and epistemological principles. And by 'solution' we understand the set of solutions of the given problem; thus the two roots of a second degree equation constitute the solution to the latter.

(A method M may be construed as a partial function from the cartesian product $2^B \times \Pi$, where B is a portion of background knowledge and Π a set of problems, into the set S of solutions. The solution to $\pi \in \Pi$ is $s = M(b, \pi)$, where $b \in 2^B$. We take the power set 2^B of B, rather than B, because every method calls for a whole set of bits of knowledge. The *M-soluble problems*, or problems soluble with the help of M, constitute a subset Π_0 of Π, such that the restriction $M_0 = M | \Pi_0$ is a bijection—i.e. one problem—one solution and conversely. In principle there is at least one method for every problem, and different methods may yield different solutions. Two methods are *equivalent* if they yield the same results. But of course they do so by introducing different intermediate steps between problem and solution. In the following diagram two alternative intermediate steps are shown.

In this commutative diagram $M_1 = F_1 \circ G_1$, $M_2 = F_2 \circ G_2$, and $M_1(\pi) =$

$$\begin{tikzcd}
& I_1 \arrow[dr, "F_1"] & \\
2^B \arrow[ur, "G_1"] \arrow[rr, "M_1", "M_2"'] \arrow[dr, "G_2"'] & & S \\
& I_2 \arrow[ur, "F_2"'] &
\end{tikzcd}$$

$F_1(G_1(\pi)) = F_2(G_2(\pi)) = M_2(\pi)$. A *tactics* is thus an ordered pair $\langle F, G \rangle$ such that $F \circ G = M$.)

Knowledge of methods is called *methodological*, and its complement *substantive*, knowledge. These two are distinguishable but not detachable, for the former is only a means for the latter, and it cannot be improved except with the help of the latter. (Imagine trying to design a new particle detector without knowing anything about particles.) Yet from the 17th century on there have been enthusiasts and even cultists of method, claiming that there is a method for every activity, and if only one hits on the right method he will perform to perfection and without any need for substantive knowledge. (An early and delightful exposition of this creed, methodolatry, was Bacon's *New Atlantis*.)

Methodolatry was badly shaken by the realization that (*a*) we know how to do a number of things without being able to formulate any explicit rules for doing them, and (*b*) we know a number of methods that often fail. Loving and building theories exemplify the former, and weighing and making statistical inferences are instances of the latter. (Recall the distinction between explicit and tacit knowledge: Ch. 2, Section 2.2.)

Methodoclasm, the opposite of methodolatry, holds either that there are no methods at all or that they are all equally fallible. This belief is even more wrong than methodolatry, for (*a*) actually there are a number of methods that work reasonably well, and (*b*) all methods, or at least the ways (tactics) of applying them, can be improved. Hence whereas the study of methodology does not produce instant scientists or technologies, its ignorance does not help discover and correct errors.

The advice often given by methodoclasts, namely "Study the history of knowledge instead of methodology", is only a partial answer, particularly because every historian writes from his own perspective, which may be more or less perceptive and tied to a more or less adequate methodology.

We do need methodology in addition to descriptive epistemology and the history of science and technology, if only because (*a*) people do not always think correctly—e.g. most of us tend to disregard unfavorable evidence and write off criticism, (*b*) there are thousands of effective techniques for analyzing statements and arguments, as well as for producing and checking data—not to speak of the uncounted methods for handling problems in pure and applied mathematics, and (*c*) the scientific method embodies certain rules of conduct that constitute the core of the ethics of science, and make it possible to search for truth.

Finally, a word on the value of methods. Each method is valuable to some extent (possibly nil) for solving problems of a given kind and with a certain aim. Change problem or goal and the method may cease to work or it may work better. (In other words, the valuation function for methods is defined not only on the set of methods but also on the sets of problems and goals.) Consequently when comparing methods we must take all three aspects into account. Thus it may happen that one method for solving a given problem is better than a second method with regard to accuracy but worse with regard to speed; or that one method is more general but also less simple than another. For example, the scientific method is the most general and accurate of all methods of inquiry, but it is also the one demanding the largest investment in knowledge and equipment.

3. APPROACH AND RESEARCH

3.1. *Approach*

An approach is—roughly and metaphorically—a way of looking at things or at ideas, and therefore also of handling problems concerning things or ideas. Take for instance the matter of pest control. The chemical approach to it results in spraying pesticides regardless of any undesirable long term consequences: it is determined by a narrow viewpoint and short term goals (saving this year's crop or favoring the chemical company). On the other hand the biological approach to pest control is determined by a broad view as well as long term goals, and it results in trying multiple biological means, such as protecting or spreading certain species-specific predators (e.g. Lady Bugs), and developing pest-resistant strains.

We shall distinguish seven broad approaches to the study and handling of things or ideas: the vulgar, doctrinaire, mathematical, scientific, applied, technological, and humanistic. The *vulgar approach* rests on ordinary knowledge, tackles both cognitive and practical problems, employs daily life procedures (in particular authority and trial and error), and is mainly interested in practical results. The *doctrinaire approach* rests on some ideology, tackles both cognitive and practical problems, resorts to authority, criticism and argument, and is mainly interested in practical results (including personal salvation and the preservation of the ideology).

On the other hand the *mathematical approach* is characterized by a formal basis (logic and mathematics), formal problems, conceptual methods, and the finding of patterns as well as the erection of formal theories. The approach of *basic science* rests on a fund of mathematical and scientific knowledge, as well as on the scientific world view, it deals with cognitive problems, employs scientific methods (in particular *the* scientific method), and aims ultimately at understanding and forecasting facts with the help of laws. The approach of *applied science* shares the basis and methods of basic science, but tackles only special cognitive problems, and aims at supplying the cognitive basis of technology. The *technological approach* is like that of applied science, but its basis includes also the fund of technological knowledge, and its aim is the control of natural systems as well as the design of artificial ones. Finally, the *humanistic* approach is based on the body of knowledge concerning human culture, it handles problems concerning intellectual and artistic culture, uses conceptual methods, and aims at understanding its referents.

In general, an approach may be construed as a body B of *background knowledge* together with a set P of problems (*problematics*), a set A of *aims*, and a set M of methods (*methodics*):

$$\mathscr{A} = \langle B, P, A, M \rangle .$$

Needless to say, every component of this quadruple is to be taken at a given time, and so is a (time dependent) collection rather than a fixed set. (Note that an approach is a projection of a conceptual framework as defined in Ch. 2, Section 4.1.)

If the background knowledge is restricted to the general philosophical framework or world view, we obtain three main types of approach: the atomistic (or individualistic or analytic), the holistic (or synthetic), and the systemic (or analytico-synthetic). The *atomistic approach* rests on an atomistic ontology, according to which the world is an aggregate of units of a few kinds, and a reductionistic epistemology, according to which the knowledge of the composition of a whole is both necessary and sufficient to know the whole. The goals of atomism are the same as those of science, and the atomistic methodics boils down to analysis into components (or the top-down method). The *holistic approach* rests on a holistic or organismic ontology, according to which the world is an organic whole that may be decomposed into large partial wholes that are not further decomposable, and an intuitionist epistemology according to which such wholes must be accepted and grasped as such rather than analyzed and tampered with. The goal of holism is to emphasize and conserve wholeness and emergence, and its method is intuition. (Actually intuition is nonmethodical: recall Section 2.1.) Finally, the *systemic approach* rests on a systemic (or systems-theoretic) ontology according to which the world is a system composed of subsystems, and an epistemology that combines realism with rationalism. Its objectives, like those of science and technology, are to understand, predict, and control. And its methodics includes analysis as well as synthesis, generalizing and systematizing, and empirical testing. (For details see Bunge, 1977a, 1977b, 1977f).

Each approach can handle only certain problems: every approach is partly characterized by its own problematics. Thus the atomistic approach can handle only questions regarding individual behavior: since it does not recognize wholes with emergent properties, it sees no point in looking for patterns of global behavior, i.e. for laws of systems as wholes or units. Likewise the problem system of holism is limited: it is hardly interested in finding out, say, the atomic composition of a molecule, or the mechanisms whereby a group of people form or dissolve a society. By contrast, systemism, or the systems approach, keeps the positive aspects of atomism and holism, and it is the approach compatible with the scientific approach. Actually it differs from the latter only in that it presupposes far less substantive and methodological knowledge.

The advantages of the systemic approach are best appreciated by comparison with its rivals. Whereas systemism treats every system as a whole composed of individuals held together by bonds (part of the system structure) and immersed in an environment, atomism neglects both the environment and the structure; holism neglects the composition of both system and environment, and does not analyze the structure; environmentalism focuses on the environment at the expense of both composition and structure; and structuralism neglects both the composition and the environment, not to speak of the history of the system. Only systemism does justice to all three aspects and their changes.

Failure to adopt the systemic approach to the study or design of systems is bound to result in failure to solve the problems concerned or, worse, in creating unnecessary new problems. For example, a marine biologist studying the migration patterns of sea lions will not make much headway unless he also studies the migration patterns of their prey. An evolutionary biologist studying the foraging abilities of honeybees will do well to study at the same time the evolution of the flowering plants preferred by bees. The archaeologist and the historian of technology cannot restrict their attention to artifacts, but must try and embed them (conjecturally) in the society that used them. The epistemologist is bound to be superficial or even utterly mistaken unless he keeps in mind that, although cognition is a brain process, it continues a tradition and it is now stimulated, now inhibited by social relations. The engineer will not succeed in designing useful large scale projects, such as dams and transportation systems, unless he cooperates with social scientists. The statesman will not introduce useful new legislation unless he realizes that every subsystem of society (the economy, the culture, and the polity) has strong links with the other subsystems of it. Although all this sounds obvious, some of it has been discovered only in recent years, and some is still to be learned by many specialists. Indeed, one may speak of the systemic *revolution*, or of the systemic approach as a new *paragon* (or paradigm). However, for the most part it is a silent revolution with but a few outspoken paladins.

In many cases, particularly in practical matters, the systemic approach violates some of the artificial frontiers between the various fields of inquiry. For example, the so-called new archaeology, that employs the systemic approach, merges history, sociology, and anthropology (cf. Sherratt (Ed.), 1980). And the new technology, that takes into account the social dimension of technical systems, is closely associated with the social sciences (see the journal *Technology in Society*). In all such cases unidisciplinarity is given up in favor of *interdisciplinarity*. In the latter approach the variables typical of a number of disciplines are not only taken into account but also interrelated: the resulting model is neither a single picture nor a mosaic of pictures but, to continue the metaphor, a sculpture. By contrast, the *multidisciplinary* approach consists in the simultaneous application of a number of unidisciplinary approaches: the result is a mosaic of pictures or models. (For an alternative analysis of these and other concepts see Jantsch (1972).) In any event, the problems concerning multilevel systems—and all problems concerning humans are of this kind—are not inherently unidisciplinary, multidisciplinary, or interdisciplinary: only our approaches to such problems can be uni, multi, or interdisciplinary. See Figure 7.5. We shall return to this theme in Ch. 14, Section 3.

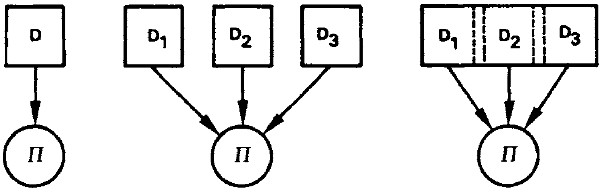

Fig. 7.5. Uni, multi and interdisciplinary approaches to a set Π of problems.

3.2. *Research*

We may speculate that understanding a problem is identical with the activity of certain psychons which, in turn, activate further psychons likely to do the job (Bindra, 1976). Thus if asked to multiply 13 by 67 the subject may choose to do so mentally, with paper and pencil, or with a calculator. In each case different psychons are likely to be activated: which ones depends on the subject's talent and experience, as well as on the instructions he has received. Likewise with problems that require research. Thus if asked to find the law of a certain process, the subject may—depending on his knowledge, intelligence, habits, opportunities, etc.—initiate a bibliographic search, or design an experiment, or sit down and speculate hoping to guess the law on the strength of a few clues such as data and analogies. In each case different psychons are likely to be activated sequentially. As the research proceeds some entirely new concatenations may occur. And, whereas certain psychons will interfere constructively with those in charge of the process, others will interfere destructively, resulting in sidetracking or halting.

Work on a routine problem may be assumed to consist in the sequential activation of a fixed set of psychons. (Analogy: groove or orbit.) Thus when psychon 1 formulates the problem, it activates (with probability near 1) psychon 2, and so on, until the target psychon—the solution—is reached. On the other hand, if the problem is new to the subject, then instead of a linear sequence or chain, a zig-zag process occurs, in which the connections between the various psychons are probabilistic rather than causal, and where the target psychon may never be activated, either because of the subject's personal failure or because the problem has no solution.

Schematically, the routine problem solving process looks like this: *Formulation–search–solution–checking*. The trademarks of this process are definiteness of formulation and near certainty of solution. On the other hand the research problem solving process looks like this: *Raw problem–choice of approach–formulation of problem within this approach–search–research plan–solution candidate–checking–evaluation.* The trademarks of this process are indefiniteness of formulation and uncertainty of outcome. (Nobel laureate Peter Kapitza (1979): "The main attraction of scientific work is that it leads to problems, the solutions of which cannot be foreseen.") In most cases the outcome proves unsatisfactory, and the process has to be repeated either partially or *da capo*, from the very choice of approach or at least from the formulation of the problem within the given approach.

There are no cut-and-dried rules, e.g. algorithms, for performing most of the operations involved in a research problem solving process. At most there are heuristic maxims and methodological rules that help design research plans. Original research, i.e. work on research problems, is zigzagging, not straight; it is chancy, not certain; and it calls for direct cooperation (e.g. of technicians or consultants) or indirect cooperation (e.g. bibliography or referees). Therefore the idea of designing a computer program embodying a "general problem solver" (Newell and Simon, 1972) is wrong-headed.

The most one can do to expedite research is (*a*) to remove obstacles (administrative, ideological, etc.); (*b*) to supply human and material resources, and (*c*) to bring to light some strategies and tactics employed in successful research, and try and clarify, justify, and systematize them—i.e. to cultivate methodology. The strategies of inquiry are the general research methods, such as the scientific method and the methods of random sampling and of mathematical modeling. As for the inquiry tactics, they are of two kinds: techniques (special methods) and heuristics. Whereas techniques are reliable procedures, heuristics are suggestions that may or may not work—such as looking for analogies with problems of known solutions, or trying to generalize special results.

The most general strategy for handling research problems, be it in science, technology, or the humanities, was indicated a while ago, but it bears repetition. It consists in the following sequence of operations:

1. *Spotting the problem(s).*
2. *Choice of approach* (which includes background knowledge, methodics, and goal).
3. *Formulation of problem* within chosen approach (i.e. transformation of raw initial problem into well defined problem).

4. *Search for existing relevant information* (i.e. scanning of background knowledge stored in theories, tables, data banks, etc.).

5. *Design of a research plan.*

6. *Implementation of plan* (conceiving hypotheses, building theories, making computations, performing measurements, designing techniques or artifacts, etc.).

7. *Trying* (checking) the outcome of previous step.

8. *Evaluation* of candidate solution (idea, data, artifact, or what have you) in the light of the background knowledge as well as the outcome of the previous step.

9. If solution is found acceptable, *extend or revise* background knowledge.

10. Otherwise *start research process again*, either replicating it or modifying some components (e.g. hypotheses or methods).

Note again the difference between a routine and an original research project. The former ends up by answering questions, the latter poses further questions even when it attains answers. (In other words, whereas routine problems are information sinks, original problems are seminal. Yet not all sources are sizable, and not all sinks are dead ends: some findings of routine research are used in further research even when they pose no new problems. Most data are of this kind.) Routine research is closed, original research open ended. The former is straight, the latter tortuous: it rarely attains its goal in a direct manner, usually it zig-zags, sometimes wanders off, and at other times derails. What one reads in the published reports is an expurgated and embellished version—which is just as well, for a faithful chronicle would be too long, convoluted, incoherent, full of uninteresting detail; and most mistakes are unenlightening except to those who make them.

(Routine research can be construed as a partial function from problems to sets of findings, or $R:\Pi \rightarrow 2^F$, where F is the set of all old and new, actual and potential, outcomes of research in the same field as Π. F does not include the null finding 0. We say that research into problem $\pi \in \Pi$ ensues in a knowledge gain $R(\pi) = f \in F$ provided $f \neq 0$. In the case of routine research the background knowledge, the methods and the aim of research are fixed and taken for granted, so there is no need to include them in the domain of R. On the other hand original research can vary these items, and results not only in findings but also in further problems. Therefore it may be construed as a partial function from quadruples ⟨bits of knowledge, problem, method, aim⟩ to couples ⟨set of findings, problem⟩, or $R:2^B \times \Pi \times M \times A \rightarrow 2^F \times \Pi$. See Figure 7.6.)

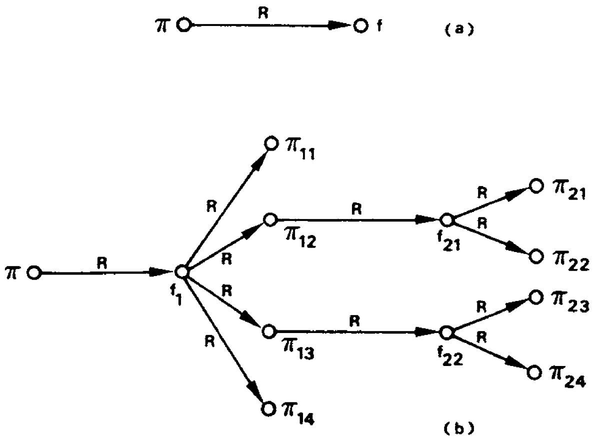

Fig. 7.6. (*a*) Routine research transforms problems into findings. (*b*) Original research transforms problems into findings or into further problems. Some problems are not investigated at all.

(The two functions, routine research and original research, may be thought to be embodied in sequential machines. Routine problem solvers may be construed as sequential machines with fixed next state and output functions: every input takes them to another state in a fixed state space, and induces an output from a fixed set of possible outputs. On the other hand original problem solvers may be regarded as probabilistic and self-organizing sequential machines, i.e. machines with variable next state and output functions, and moreover probabilistic functions. However, such devices are not machines proper, for there is no way to design or program a machine to enlarge its own state space, or create its own next state and output functions, but to specification—in which case it is a routine not an original problem solver.)

Our description of the general strategy for handling research problems tells us *what* is to be done but not *how* it is to be done. The how is a matter for *heuristics*, or the art of problem handling. The following heuristic suggestions may help go through the research problem solving process. (See Pólya, 1954, 1957; Bunge 1967a.)

1. *Search for a good problem*

Scan the background knowledge for a gap that you feel is worth filling and you might fill yourself.

Consult with coworkers or assistants, colleagues or teachers.

Pay no attention to pessimistic advice if you feel sure you have got hold of a good problem and can afford to fail in the attempt to solve it.

2. *Choose the right approach*

Start by locating the problem in a discipline or a group of disciplines.

Adopt an approach—basic or applied, atomistic or systemic, etc.

Determine the minimal background knowledge required to handle the problem.

Find out the recent history of the problem or that of its predecessors.

3. *Locate the problem*

Determine whether the problem is one of original research or routine, substantive or methodological, conceptual or empirical.

4. *State the problem clearly*

Minimize the vagueness of concepts and the ambiguity of signs.

Select adequate symbols—as simple, suggestive, and standard as possible.

Draw sketches or diagrams, build preliminary scale models, or make preliminary calculations.

5. *Make a further study of the problem*

Identify the premises and the unknowns.

Unearth the most important presuppositions and examine any that look suspicious. (As a result you may decide to switch to another problem, e.g. the problem of reconstructing such presuppositions.)

Eliminate the redundant information ("noise").

Compress and simplify the data.

Formulate and organize your preliminary hypotheses and rules of procedure.

Introduce simplifying assumptions or devices.

Look for similar solved problems or subproblems (components of the given problem).

Vary the constituents or the formulation of the problem, in an attempt to transform the given problem into a homologous problem in an adjoining field.

6. *Design a research project (plan, program)*

Reexamine and reorganize your preliminary hypotheses and rules of procedure.

Organize the steps of the proposed research process according to their logical priority (A logically presupposes B), epistemological priority (Knowledge of A presupposes that of B), or pragmatic priority (Doing A requires doing B first).

Choose the technique adequate to the nature of the problem and the kind of solution wanted.

Estimate the possible advantages and shortcomings of the various available techniques, if there are any.

In case no technique is available, state the strategic problem of devising one, and attack this one first.

Choose the materials—drugs, animals, locations, etc.—and the instruments—centrifuges, thermometers, computers, etc.—likely to be used.

Choose the coworkers, assistants, and technicians.

Secure the financial means.

Make provisions for the unexpected—in particular for changes in plan or even in problem.

Be prepared to have your project rejected for being either too poor or too good.

The preceding operations constitute the preliminary stage of the problem-solving process. Although they do not solve the problem, they do prepare it for attack, and they gather all the means likely to be required to solve it—or to show that the problem has no solution with such means. Actually the preliminary stage is usually the most difficult of all: a correct statement and a good strategy is half the solution. No wonder then that such preparation may consume as much time and ingenuity as the implementation of the research project.

The question of formulation is so important that we must insist on it, the more so since most problems in everyday life can be solved without formulating them explicitly, for we have learned well-tried routines to solve them. Other problems must be formulated explicitly if only because they admit of alternative formulations and therefore alternative solutions. (Better: a raw problem is actually a whole set of well formulated problems.) For example, if we wish to find out where two curves meet, we must either draw the curves (obtaining an approximate solution) or solve a certain equation. If we wish to find out whether a given material conducts electricity, we may insert it in an electric circuit and touch it (at our peril) or watch whether the pointer of the ammeter moves—or make assumptions about the composition and structure of the material, and compute its conductivity with the help of quantum mechanics. In science, technology and the humanities all problems have to be formulated explicitly and with maximum clarity. Such formulation (or refinement of the raw initial problem) is seldom unique: it depends on the state of the art as well as on the outlook, experience, talent, and aims of the investigator. (For the importance of such personal factors see Polanyi (1958) and Holton (1973).)

The preliminary study of a problem culminates in a *research project*, plan or program. Any such project looks, in a nutshell, like this: Given a certain background knowledge b, and an approach a, attack problem π on the basis of programmatic hypothesis h, aiming at goal g, and using means (among them methods) m (available or to be produced). In short, a research project is a sextuple $p = \langle b, a, \pi, h, g, m \rangle$. *Example 1*: Given the available body of sociological knowledge, and ordinary mathematics, and adopting the systemic approach, build a comprehensive theory of social relations, on the basis of the programmatic hypothesis that all social relations are either interpersonal or intersystemic; the goal is to explain social behavior, and the means the standard method (or style) of model construction in the "hard" sciences. *Example 2*: Given the available body of neurophysiological and psychological knowledge, and adopting the bottom-up approach, identify the neuronal systems involved in thinking abstract ideas, on the basis of the programmatic hypothesis that thinking is the specific function of certain plastic neuronal systems; the goal is to furnish a deep explanation of thinking, and the means all the paraphernalia of neuroscience, experimental psychology, and mathematics.

Every independent investigator has some research project or other, whether original with him or supplied by somebody else—laboratory director, thesis advisor, senior colleague, etc. If vast and ambitious, a research plan is likely to be shared by, or passed on to, other investigators. And, on important issues, several competing research projects may be at work contemporaneously. Hence every field of active inquiry may be viewed as a changing bundle of more or less interdependent research projects in progress. (There is no harm in duplication: on the contrary, duplication is necessary for control.)

The way to become an investigator, i.e. to master the craft of research, is not by becoming acquainted with instances of good science—e.g. by reading history of science—or with methodology—e.g. by reading this book. Both help but neither is a substitute for participating in a research project at the knee of some master—much the same way that craftsmen and artists learned their trade in the Middle Ages and the Renaissance. The reason is that learning to do research is not just acquiring some information but rather acquiring certain habits, attitudes, and aspirations—all of which are a matter of know-how.

General methodology cannot go much further into the matter of handling problems. Any more specific suggestions would take us into specific branches of research. For example, a useful heuristic rule in applied mathematics is: "If a term of the form $A_x B_y$ occurs in a calculation, try adding $-A_y B_x$ to it, for the result is the z-component of the vector product of A and B". Biologists use Cuvier's rule: "If two organisms (or fossils thereof) exhibit two homologous traits, look for more". Historians make use (and often abuse) of the rule: "Look for precursors of every novelty". And doctrinaires abide by the rule: "Distrust all new ideas or behavior patterns". There are hundreds of special heuristic rules of this kind, which methodology has yet to gather and study.

4. ANALYSIS OF PROBLEMS

4.1. *Logic and Semantics of Problems*

We proceed now to a logical and semantical analysis of problems. Ordinary logic and semantics do not account for them because they are not propositions and therefore can be neither true nor false. Nor can linguistics help, for problems can be expressed either by interrogatives or by commands or even by sentences. Thus 'What was that?', 'Find out what that was!', and 'You are being told to find out what that was' express the same problem. The only reasonable approach to the analysis of problems is epistemological, i.e. to regard them as the starters of inquiry processes. This is the approach adopted in an earlier work (Bunge, 1967a, Ch. 4), which we shall now review and complete.

To begin with, problems do not come in isolation but as components of approaches. Recall that we defined an *approach* as a quadruple ⟨*Background knowledge, Problematics, Aims, Methodics*⟩ (Section 3.1). But of course not every problem stands out against the entire background knowledge: only a part of the latter is required to pose and solve a problem. We call this part the *setting* or *context* of the problem. More precisely, the setting or context of a problem in a given approach is the collection of components of this approach that are related in some way (logically, semantically or pragmatically) to the concepts occurring in the formulation of the problem. For example, one suitable setting for investigating the mechanism of problem finding and solving is neuropsychology; another is the sociology of knowledge; a third is the history of knowledge.

In principle every problem can be approached in more than one manner, and so it has more than one setting. Thus the problem of how to eliminate poverty belongs to, or arises in, ethics, ideology, politics, and applied social science. Because a problem may belong to different contexts, it may receive different solutions. For example, drug abuse is seen in a biological setting as an instance of addiction, in a medical setting as a matter of cure, in a legal setting as one of legislation and law enforcement, and so on. Each setting suggests the way to handle the problem.

Although a problem can be approached in alternative ways, these are not always equally suitable. In some cases one of the approaches is preferable to the others, and in other cases the merging of several approaches is desirable. For example, the problem of the origin of life is approached differently in science and in religion. The former approach invites making conjectures and experiments on the self-assembly of biomolecules, organelles, and eventually cells; on the other hand in many religious approaches the matter is one of faith in some dogma or legend about a divine *fiat*. In this case, then, the scientific approach will be preferred only by those who prefer truth by research to truth by revelation. In other cases different approaches are equally legitimate but partial, and must therefore be joined. Any social problem, such as poverty, ignorance, or delinquency, is a case in point: none of them can be solved within a single setting, but every one of them calls for interdisciplinary studies and measures.

In some cases the context of a problem must be shifted. Thus when a mathematician is summoned to help with a scientific or technological problem, he treats it as a problem in pure mathematics, i.e. he drops the factual interpretation of the concepts involved. For example, time will be for him just a real variable, and an equation of motion just one more equation to be investigated on its own mathematical merits. Likewise the biochemist moves biological problems over to chemistry, by reducing them to chemical reactions and studying them *in vitro*. A similar shift of context occurs when science is applied. For example, the phytotechnician must "translate" the results of the genetics laboratory into cultivation methods, crop yields, and so on. All these are cases of problem relocation or *recontextualization*.

In sum, every problem arises in some context or other—or, equivalently, it is a component of some approach or other. And it can be moved to some other context, not necessarily to advantage. There are no problems out of context, but the various possible approaches to a problem may not be equally suitable for a given purpose. And sometimes a systemic approach, involving the joining of a number of contexts, is required.

Our next task is to analyze the internal structure of problems. We postulate that every problem has three constituents: presupposition(s), generator, and solution (Bunge, 1967a, Ch. 4). Consider the problem "What thinks?", i.e. "What does the thinking?". It presupposes (takes for granted, does not question, assumes the premise of) the existence of some entity, be it the brain or the mind, that does the thinking. It is generated by the predicate "thinks", for the unknown to be uncovered occurs in the underlying formula "x thinks", or "Tx" for short. And the problem induces research resulting in a solution of the form "b thinks", or "Tb", where 'b' names a definite individual—someone's brain or mind. In other words our problem is "Which is the x such that x thinks?", which we symbolize '$(?x)Tx$'. The presupposition of this problem is "Something thinks", or "$(\exists x)Tx$", the generator is "T", and the solution "Tb", or simply "b". Logically, then, we have the sequence: *presupposition–generator–solution.* We may identify each class of problems with such a sequence.

In general, every problem is posed against a certain background of antecedent knowledge. This background contains the context or setting of the problem, and in particular its presuppositions. The latter are the propositions (data or hypotheses) that are somehow involved though not questioned in the inquiry prompted by the problem, although they may become the subject of alternative inquiries. The problem may be regarded as generated by a set of open formulas (what used to be called 'propositional functions') exhibiting gaps in knowledge, i.e. unknowns, that are to be filled by research. The formulation of the problem results, formally, from applying the operator "?" one or more times to such formulas. However, "?" is an epistemological operator, not a logical one: it means "search for" without even intimating how to conduct the search. Finally, research on a soluble problem yields eventually another set of constructs—the solution to the problem—which, when substituted into the generator, turn the latter into a set of statements that can be assigned a definite truth value.

The notion of presupposition of a problem occurs in the following definition of the important concept of meaningfulness of problems. Let C be a context included in a given body B of background or antecedent knowledge. We stipulate that problem π is *well conceived* in C only when the following conditions are jointly fulfilled: (i) π belongs to some approach $\langle B, P, A, M\rangle$ including (actual or possible) methods in M capable of handling π; (ii) all the concepts occurring in π occur also in C, hence in B, and (iii) the presuppositions of π are compatible with C. (We require the latter to rule out crackpot questions, and do not require compatibility with the entire background B, to allow for revolutionary questions.) Otherwise π is *ill conceived* (or *makes no sense*) in C. Thus the problem "When did God create man?" is ill conceived in modern biology, which does not contain any concept of divinity, and asserts that man was not created but evolved from ape-like ancestors. In general, theological questions are meaningless in the context of science and conversely. (More in Ch. 14, Section 4.2.)

At first sight such statements as "Where is p?", "When does p happen?", "Is p true?" and "Is p valuable?" do not fit the above schema, for they seem to be generated by p itself, which is now a thing, now an event, now a proposition, now any object. Yet such problems, when restated explicitly. do prove to fit our schema. Thus "Where is p?" is best reformulated as "What are the values of the coordinates of p relative to such and such reference frame?", or $(?v)(V(p) = v)$ for short, where in this case v is a triple of real numbers. Likewise "Is p true?" is best construed as "What is the truth value of p relative to such and such body of knowledge?", or $(?v)(V(p) = v)$, where now v is any real number included in the interval $[0, 1]$. Every one of the above problems presupposes something or other—e.g. that every thing is at some place (relative to some frame), or that every proposition can be assigned a truth value (relative to some body of knowledge). And they are all questions about the value of some individual variable or other, even if the variable is hidden at first sight.

Not all problems concern individual variables or unknowns: in some cases the blanks to be filled are predicate variables. For example, the problem "What is b?" directs us to search for the cluster of properties P, so far unknown, possessed by b. This problem may be symbolized by '$(?P)Pb$', which points to the unknown P, a conjunction of attributes. Questions asking for the value(s) of one or more individual variables shall be called *individual problems*, whereas questions asking for the value(s) of one or more predicate variables shall be called *functional problems*. We assume that every elementary problem is of either of these kinds, and every complex problem a combination of problems of either kind. We shall deal below with simple and complex problems.

What about problems of the form "Does b have the property B?", in which no variable is in sight? The variable is hidden: it is the truth value of the proposition "b has the property B". In other words, the given problem is actually of the form $(?v)(V(Bb) = v)$, where V is a truth valuation function. The problem consists in finding out the precise value of v.

Similarly, all questions concerning existence can be regarded as problems about the truth values of the corresponding existence statements. Thus "Are there free quarks?" can be restated as "Is it true that there are free quarks?", which in turn is rendered explicit by "What is the truth value of the proposition that there are free quarks?". Similarly with questions concerning universality. For example, "Does every thing change?" is equivalent to "Is it true that every thing changes?", which in turn may be restated as "What is the truth value of the thesis that every thing changes?". The moral we extract from examining the above cases, characterized by the seeming absence of variables, is this: Do not allow language to mislead you—*cherchez la variable.* Note also that the question mark bears always on some unknown or variable of either the individual or the predicate type. (Furthermore "?" does not bind the variable on which it acts. Only the solution should be free from unbound variables, i.e. it should be of the general from Bb, where B is an n-ary predicate and b an n-tuple of individuals.)

(The question mark, which so far we have left undefined, can be partially defined as follows. We start by abstracting from the variable type, writing an arbitrary elementary problem in the form: $\pi(v) = (?v)G(v)$, where v is the only variable and G the generator. Our new formula subsumes both elementary problems of the individual type, i.e. $(?x)Bx$ with a fixed B, and elementary problems of the functional type, i.e. $(?X)Xb$, where b is a fixed individual. Although these problems are very different, they are equivalent in the sense that they have the same solution, namely Bb. Further, let $R{:}\,\Pi \rightarrow 2^F$ be the routine research function introduced in Section 3.2, that represents an inquiry process as a mapping from problems in Π to sets of findings in F. We stipulate the partial implicit definition

$$R(\pi) = R[(?v)G(v)] = Bb,$$

i.e. research on a problem yields the solution to the latter.)

(The generalization to a research or original problem is straightforward. In this case, as we saw in Section 3.2, the outcome of research is in general an ordered couple $\langle$Finding, New problem$\rangle$—where the finding is occasionally that the problem is not soluble with the indicated means. The case where no new problem arises is $\langle$Finding, Null problem$\rangle$, where *Null problem* $= (?x)Ox$ or $(?X)Xo$, and in turn O is the null predicate—attributable to no individual—and o the null individual—to which no predicate except O is attributable. Likewise, if the only result is a new problem, we write: $\langle$Null finding, New problem$\rangle$, where the null finding is the one not in 2^F.)

The individual/functional dichotomy of problems cuts across many other classifications. For example, Aristotle distinguished between *what*-problems, or questions of fact, and *whether*-problems, or dialectical (logical) problems; and Pólya (1957) between *problems to find* and *problems to prove*. We shall not enter into this matter but shall comment instead on four kinds of problem that are of particular philosophical interest: inverse, why, what-if, and existence problems.

The *inverse* or *dual* of a problem is one where the data of the latter are the unknowns of the former and conversely. Thus if computing a value of a function is a direct problem, then calculating the argument(s) from the value is the corresponding inverse problem. Here is a small random sample of pairs direct-inverse problems. Given an equation, find its solutions; given a function, find the equation it solves. Given a theory, check a theorem in it; given the latter, find whether it is a theorem of a given theory (i.e. solve the completeness problem for the latter). Given the mass of a particle and the force(s) acting on it, find the particle trajectory; given the mass and the trajectory, find the force(s).

The last mentioned example illustrates a very common situation in all fields of inquiry, that of analysis and synthesis. The *analysis* problem is: Given a system (i.e. knowing or assuming its composition, environment, and structure), find its behavior. The inverse problem is that of *synthesis*: Given a behavior, find or design a system that realizes it. For example, find a kind of molecule or material, machine or cultivar, social system or teaching method, that will behave in a prescribed way or achieve given goals. Typically, the problems of technology and of social action are synthesis problems; with luck they are the inverses of scientific problems with known solutions. As a rule inverse problems are far harder than the corresponding direct problems, if only because they usually have multiple solutions.

Thus think of the following problem pairs. (*a*) Direct problem: Given a body, a screen, and a projection method, find the projection or shadow of the body on the screen; inverse problem: given the projection on the screen (e.g. a photograph) and the projection method, reconstruct the body. (*b*) Direct problem: Given a social policy, find the state of the society resulting from its application; inverse problem: given a desirable state of society, find a social policy likely to achieve it. (*c*) Direct problem: $(?x)(\sin b = x)$; inverse problem: $(?x)(\sin x = b)$ or, in an equivalent notation, $(?x)(sin^{-1} b = x)$. In this case the direct problem has a single-membered solution, for *sin* is a function; but, because *sin* is not a 1:1 function, the inverse problem has a multiple—in fact an infinitely-membered solution. (If a is a solution to it, so is $a + 2n\pi$, where n is an arbitrary integer.) So much for the fascinating and ill-studied problem of inverse problems.

Why-problems are of the form "$(?p)\ (p \vdash q)$", i.e. "What premises p entail the given q?". This is the kind of problem that the theory builder faces: his givens are low level generalizations, and his desideratum is to invent high level generalizations entailing the low level ones. (More in Ch. 10.) *Why*-problems are the inverses of *what-if* problems, which have the form $(?q)\ (p \vdash q)$, or "What are the consequences of p?", or "What would happen if p were the case?". These are dialectical problems, or problems to prove. What-if questions fall into two kinds: those with false and those with true presuppositions. "What if we could live without eating?" illustrates the former kind. Such questions generate fiction rather than knowledge. On the other hand a problem such as "What if the nebular red shift were due to some cause other than the expansion of the universe?" violates no known law of physics and is fruitful, for it suggests inquiring into the possibility of a cosmology without the Big-Bang.

Existence questions are among the most difficult of all. They can be formulated thus: "Are there objects of kind K?", or, more generally, "Are objects of kind K possible?" where K is determined by fairly exact predicates. That question can in turn be restated as "What is the truth value of the statement that K is or could be nonempty?". They are of two main types: formal (e.g. existence of solutions to a given equation) and factual (e.g. existence of a planet). Consequently they are to be investigated conceptually in the former case, and empirically as well as conceptually in the second. (Recall that the expression 'exists' is ambiguous.) In science and technology existence (or possibility) problems are not whimsical: there is always some ground to conjecture that something exists or may be brought into existence. And answering such question is prior to asking the more specific question 'How do K's exist?', or 'How are K's possible?'.

Factual existence problems can in turn be classed in various ways, e.g. thus: (*a*) the most general ontological existence problem: 'What kinds of thing are there (really)?'; (*b*) scientific existence problems, of the form "Does the such and such exist?"; (*c*) the general epistemological existence problem, "To what may we legitimately attribute existence?"; (*d*) the most general technological existence problem, "What kinds of thing can we design and bring into existence?"; (*e*) special technological problems, of the form "Can we design and construct such and such things?"; (*f*) the most general ethical existence problem, "What ought we to bring into existence?"; and (*g*) special ethical existence problems, of the form "Ought we to bring such and such into existence?".

The ontological question is wider than the partial scientific existence problems. (It would seem that there is a prior ontological problem to be solved, namely "Why is there something rather than nothing?" However, this problem makes sense only in a non-naturalistic context, for it presupposes that there is a Creator and that it might have been possible for Him not to go to the trouble of making the world. The problem makes no sense in a naturalistic ontology, let alone in science.) The epistemological question has a deceptively simple answer: We can attribute existence to whatever exists really. This answer is unhelpful, so we must settle for a weaker one, namely: We may attribute real existence to whatever we have good empirical, and if possible also theoretical, grounds to conjecture that it exists. (For a definition of real existence see Bunge (1981a).) The general technological question is of course broader than any specific technological problem such as "Are there antidotes to such and such poison?" or "How is that subject best taught to undergraduates?". The same holds for the relation between the general and the special ethical questions. But what is such a relation between a general and a special problem, or between a problem and its subproblems if any? Let us find out.

Consider any two problems. We can form a third problem out of them if we set up the task of solving one *or* the other, and a fourth problem if we propose to solve the one *and* the other. We say that in the first case our compound problem is *disjunctive*, in the second *conjunctive*. The solution to a disjunctive problem is the disjunction of the solutions to its components, whereas the solution to a conjunctive problem is the conjunction of the solutions to its components. And we form the *negate* of a problem if we negate its generator. The solution to the negate of a problem is the negation of the solution to the problem.

The three operations can be combined in a number of ways to form problems of any complexity. Conversely, a complex problem can be analyzed in terms of the disjunction, conjunction, or negation of elementary problems. For example, the algebraic problem $(?x)$ (x is a complex number & $x^2 + x - 2 = 0$) can be rewritten: $(?x)\,[\mathbb{C}x \,\&\, (x-1)(x+2) = 0]$, and thus be decomposed into two elementary problems, namely $(?x)$ $(\mathbb{C}x \,\&\, x - 1 = 0)$ and $(?x)$ $(\mathbb{C}x \,\&\, x + 2 = 0)$. The original problem is thus seen to be of the disjunctive type, and its solution: $(a=1) \vee (b=-2)$. Whereas sometimes it pays to analyze a complex problem into its constituents, at other times it is advantageous to switch from a problem to its negate. Thus to find out whether a given person is celibate we may assume that she is married, and search for her spouse; likewise to find out whether a thing is far away we had better start by exploring the neighborhood.

(The three operations on problems which we have just introduced may be symbolized as follows. Let $\pi(v)=(?v)Gv$ be a problem with generator G and solution $G(a)$. Then the negate of the problem is defined to be

$$-\pi =_{df} \neg G.$$

Call now $\pi(v_1)=(?v_1)G_1(v_1)$ and $\pi(v_2)=(?v_2)G(v_2)$ two problems with solutions $G_1(a)$ and $G_2(b)$ respectively. Then the disjunction and the conjunction of these problems are defined as

$$\pi(v_1) \curlyvee \pi(v_2) =_{df} [G(a,b)=G_1(a) \vee G_2(b)],$$

$$\pi(v_1) \curlywedge \pi(v_2) =_{df} [G(a,b)=G_1(a) \& G_2(b)],$$

respectively, where $G(a,b)$ is the solution to the corresponding binary problem.)

On the basis of the three operations on problems, which we have introduced, more complex problem forms can be produced and analyzed. Also, the very concept of a complex problem can be defined, namely thus: A *complex* (or *compound* or *molecular*) problem is one where either the negation or the conjunction or the disjunction of problems occurs. The definition of the dual concept is obvious: a problem is *elementary* (or *simple* or *atomic*) if it is not complex. Sometimes it pays to increase the complexity of a problem, as when an insoluble problem about real functions is translated into a soluble one about complex functions, and when an economic problem is regarded as just one component of a complex social problem. However, most of the time we wish to simplify problems by analyzing them into disjuncts, conjuncts, or negates. Thus a triatomic problem may be analyzed into a disjunction of conjunctions. (In effecting such analyses we assume the associativity and commutativity laws; we also assume that disjunction distributes over conjunction and conversely.)

Besides the three operations on problems, we introduce three useful relations between problems: those of implication, equivalence, and entailment. We stipulate that a problems *implies* a second problem if the generator of the first implies that of the second, and that two problems are *equivalent* if their generators are. We also stipulate that a problem *entails* another problem if the generator of the former entails that of the second, i.e. if the solution to the second follows from that to the first. Finally, we say that a problem is a *subproblem* (or *special case*) of another problem if the second implies or, in particular, entails the first. For example, every homogeneous equation is a subproblem of any number of inhomogeneous equations, and the problem of minimizing alienation is a subproblem of that of maximizing participation.

We can now lay down rules for the proper formulation of problems:

Rule 1: A problem π is *well formulated* (or *proper*, or *sound*) in a context C iff

(i) π is well conceived (or makes sense) in C (see the definition of this concept at the beginning of this section);

(ii) the generator of π contains as many variables and question marks as unknowns—i.e. the statement of the problem indicates explicitly what is to be sought;

(iii) π is elementary (or atomic) of the individual or the functional type, or is a combination (by means of the operations of disjunction, conjunction, or negation) of elementary problems.

A well formulated problem is determinate or well-defined: if soluble at all with the given means it will have a unique (though possibly many-membered) solution. And, by displaying all the relevant items (the data and unknowns), as well as their relations, it should suggest the type of inquiry needed to solve it. For example, a system of m linear equations in n variables (unknowns) is *determined* if and only if $m = n$, *underdetermined* if $m < n$, and *overdetermined* if $m > n$. The problem is well formulated only in the first case. If it is underdetermined, it has no unambiguous solutions—or, if preferred, it has too many solutions. If it is overdetermined it has no solutions at all (unless some of the equations are redundant). Therefore if the problem is underdetermined we must try and get further equations or eliminate some variables. And if the problem is overdetermined we must try and reduce it to a determinate problem by eliminating $m - n$ equations.

Rule 1 should be helpful to weed out ill-formulated problems but it cannot be expected to lead to formulating good problems in the sense of Section 1.2. It does not even guarantee the formulation of well conceived problems, because it is always difficult to unearth and examine all the relevant presuppositions. Even in a highly formalized theory only those presuppositions that have been identified by the theorist are listed. Except in trivial mathematical cases, every list of presuppositions is likely to be incomplete. Although this incompleteness causes sometimes the problem to be ill-conceived, the very discovery of such incompleteness may be the source of interesting new problems.

So far we have dealt with isolated problems. But in ordinary life and in research fields problems come in clusters, not in isolation. This is particularly true of original research in science and technology, where every problem has some precursor and triggers research ending up in further problems. (This is what is meant by the popular saying 'Everything leads to something else'.) Thus "What is it like?" precedes both "How did it evolve?" and "What is it for?". The precedence in question is epistemological in the case of cognitive problems: we must solve certain problems before being able to attack others. And it is pragmatical in the case of practical problems: we must make certain means available before we may endeavor to attain certain ends.

So, every problem, whether cognitive or practical, belongs to some *branching sequence* of problems, i.e. a partially ordered set. Discovering, planning or manipulating such partial orderings of problems is part of the strategy of research or of action. Such strategy must be sketched, if only to be modified whenever necessary, unless the search or the action are to be haphazard and therefore inefficient. Evidently, the ordering relation is this: a problem *precedes* another if solving the latter presupposes solving the former—i.e. if the solution to the first is used to solve the second.

(In the case of cognitive problems this relation can be elucidated thus. Let C_1 and C_2 be the contexts or settings of problems π_1 and π_2 respectively, and call $G_1(a)$ and $G_2(b)$ their respective solutions. Then $\pi_1 < \pi_2$ iff $G_1(a)$ is in C_2. In particular, if the problem is one of proving, C_2—which includes $G_1(a)$—entails $G_2(b)$. In the case of practical problems we can say that $\pi_1 < \pi_2$ iff the solution to the first problem is among the factual conditions—causes, actions, materials, or what have you—needed to bring about the solution to the second problem. Since practical problems are concerned with the modification of some concrete system or other, problem precedence amounts to this: $\pi_1 < \pi_2$ iff the system has to attain the state associated with the solution of π_1 before it can reach the state associated with the solution to π_2.)

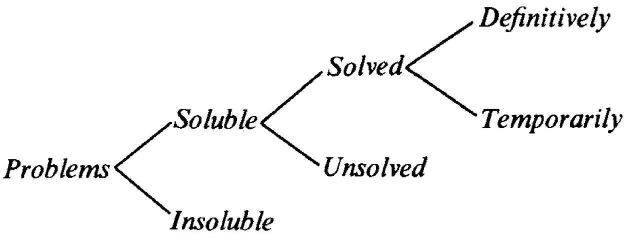
(Actually problem clusters are richer than ordered sets: they are *networks*. In fact, given any problem we can form its negate, and given any two problems we can form their disjunction and their conjunction; besides, problems come in direct-inverse pairs. This suggests defining a *problem system* as a nonempty set of problems, ordered by the relation of problem precedence, together with the operation of problem disjunction, conjunction, negation, and the still unclear operation of problem inversion. The algebraic structure of such a system is yet to be investigated.)

We postulate that *every research problem belongs to some problem system.* A corollary of this assumption is that no research problem can be solved unless some other components of its system are attacked as well—some before, others at the same time. Thus the problem of synthesizing a living cell requires the solution of hundreds of problems in molecular biology, biochemistry, cell biology, evolutionary biology, instrumentation, etc. And the energy crisis cannot be solved by adopting a single measure, for it belongs to a vast problem system composed not only of technological problems but also of economic, political and cultural ones. The mere realization of the systemic character of research problems would facilitate research and expedite social readjustments.

4.2. *Solved, Unsolved, Insoluble*

Not all problems, even if well formulated, are soluble; and those which are can be solved with certain data (or assumptions) and methods but not with others. Solubility is relative to data (or assumptions) and methods rather than absolute. Thus the problem of the quadrature of the circle cannot be solved with ruler and compass but is easily solved analytically; and the problem of communicating with the deaf-mute cannot be solved using oral language but is solved by means of sign language.

In regard to their solubility problems can be classed as follows:



Except for routine problems it is impossible to prove conclusively that a given problem is soluble—short of solving it. On the other hand it is sometimes possible to prove that a problem is insoluble in a certain manner—e.g. exactly, or in a single manner—with the help of certain data (or assumptions) and methods. For example, we cannot measure simultaneously the exact position and momentum of an electron because it does not have them; we cannot build a perpetual motion machine because energy is conserved in a closed system; and we cannot communicate with the dead because the dead happen to be dead.

All of the above are examples of total insolubility or, if preferred, of ill-conceived problems or even pseudoproblems. They are not insoluble for want of knowledge but because the world is the way it is. (For example, we cannot communicate with the dead because only the living brain is capable of thinking, and thought can be communicated only through the senses.) They are not permanent mysteries such as those of religion, which are supposed to be beyond the reach of reason and experience. Nor are they relative mysteries such as most murders, which could be solved with some more inquiry. They are just nonproblems.

The genuine but insoluble problems are those the metamathematicians call 'unsolvable': they can be *proved* to be such. For example, Gödel proved the existence of statements that are not provable within certain theories, namely all those containing arithmetic. He did not exhibit any specimens of such statements but just proved that they exist (formally), so his proof did not affect the working mathematician. Still, it undermined the faith that every mathematical problem can be solved within some theory. In factual science and in technology we cannot prove any problem to be unsolvable. Here we know that, whereas some problems have been solved, if not completely and exactly at least partially and approximately, others remain unsolved or even unstated. In factual science and technology we have no mysteries but only unsolved problems.

Here is a random sample of scientific problems still unsolved, or solved only partially, by 1983. Is the universe spatially finite or infinite? Are there black holes? What are quasars? What is the precise origin of cosmic rays? Are there reliable earthquake predictors? What caused the various glaciations? What is the function of the neutral mutations: important or insignificant? What is the function of "selfish genes" (that do not transmit hereditary traits)? Why are most molecules in organisms L-active? Does bioevolution proceed always gradually or is it punctuated by macromutations? At what point does a variety become a species? Is geographic isolation necessary for speciation? What caused the extinction of three-quarters of the biospecies at the beginning of the Tertiary era about 65 million years ago? Why do we have only half as many genes as frogs do? What is the precise lineage of our species and, in particular, whence, when and how did the most primitive *Homo* emerge? Why do all higher vertebrates sleep? Why do most people retain their most important beliefs in the face of refutation? How do we think? How do we learn to talk? Why are some people more interested in solving problems than in nursing beliefs? What are the factors of social cohesion? Are there natural laws of the economy? Are there laws of history? How did capitalism originate? Is socialism compatible with democracy?

All of the above problems are being investigated at the time of writing, and some of them have given rise to heated controversies. Few scientists believe that there are cognitive problems both well formulated and insoluble, i.e. absolute mysteries: they leave irrationalism to theologians and philosophers. Not that it can be proved that all of the above problems are soluble: this is a matter of faith, not proof. (Solutions, not problems, are subjected to proof or disproof, conclusive or otherwise.) Yet this is no naive (uncritical and groundless) faith but one that can be justified in various manners.

First, there is the past success of inquiry every time it has been conducted scientifically and been allowed the freedom to do so. Second, there is the enormous capacity of the human brain to form and dissolve neuronal connections, to activate itself, to respond to novelty, and to seek it. Third, society needs more cognitive problem finding and solving if it is to face its most pressing problems. (Not that science can tackle practical problems, but it does produce some of the knowledge needed to solve some of them.) In short, optimism in the capacity of research is well founded. (Whether research will continue to be conducted is another question to be addressed in Ch. 13, Section 4.) Without such rational faith in research no long term research project would ever be undertaken. Radical skeptics and dogmatists have no such faith and as a consequence they never discover or invent anything but errors in others.

Our faith in inquiry, though great, is not boundless: it is tempered by the following facts. First, many solutions that seemed flawless at the time they were obtained turn out to be defective in some way or other (even in pure mathematics); consequently they have to be repaired or even abandoned. Second, some problems are given up before they are solved, either because they fall out of fashion, or because they are intractable with the available means, or because they are seen to be unimportant, or because of new unfavorable cultural or political circumstances. Third, there are limits to the information we can obtain and to the number of problems we are capable of tackling: we are not omniscient and we do not want to know everything that can be known. (Information overload can be as bad for original research as lack of information, for it is confusing and inhibiting. And lack of information is sometimes unavoidable, particularly regarding past events: their traces have often been obliterated by other events, so there is no record to be studied.) Fourth, there are certain problems that, because of their breadth and depth, are likely to stay with us forever: they are the scientifico-philosophical and technico-philosophical problems.

Think of "What is matter?", "What is spacetime?", "What is life?", "What is mind?", "How can we know?", "What can we know?", "What is good?", "What can we do and what ought we to do?", and "What does the good society look like?". These are not mere puzzles, let alone illegitimate philosophical questions, as the pseudoanalytic counter-revolution in philosophy has labelled them. (Cf. Warnock, 1958.) Nor do they arise from a misuse of words, so they will not be solved, let alone dissolved, by linguistic analysis—the way Wittgenstein and his disciples would have us deal with philosophical problems. (Remember the famous pronouncements: "philosophical problems arise when language *goes on holiday*"—Wittgenstein, 1953, p. 19—"the clarity we are aiming at is indeed *complete* clarity. But this simply means that the philosophical problems should *completely* disappear"—*ibid.*, p. 51—and "The philosopher's treatment of a question is like the treatment of an illness"—*ibid.*, p. 91.)

Those wide scope problems are the very *raison d'être* of entire disciplines, and they are unlikely to receive final solutions even though they are being investigated and progress is being made in solving them. All grand problems are like hydras: as one head is cut another sprouts. But, unlike Hercules' hydra, they will continue to defy mankind as long as there are curious people left. Progress changes the problematics without shrinking it. On the contrary, the more we get to know, the more and tougher problems can we formulate. Progress in any epistemic field is measured not only by the problems that get solved but also by the unsolved problems that are being investigated.

As long as there are rational beings they will face and seek problems of various kinds: (*a*) *practical* problems affecting individuals and social systems; (*b*) *cognitive* problems of either the substantive or the methodological kind—or, in a different classification, empirical or theoretical; and (*c*) problems of *valuation and morals*. A correct, even if only approximate, solution to problems of any such kinds requires some knowledge, sometimes available, mostly to be sought. Moreover, the investigation of any problem of some kind poses further problems of different kinds. Thus practical and moral problems require some substantive knowledge, and the investigation of cognitive problems requires abiding by certain methodological and moral norms. In short, the composition of each problem system is heterogeneous. The heterogeneity is sometimes such that it calls for a multidisciplinary or even an interdisciplinary approach.

5. CONCLUDING REMARKS

What distinguishes modern thought from that of our ancestors 50,000 years ago is not so much better brains as the kind of problems some of us tackle and the way we approach them. Whereas our remote ancestors presumably devoted their whole brain power to solving day by day survival problems, agriculture and village life gave some people, from about 10,000 B.C. on, enough leisure to apply their wits to speculative problems, as well as to try and solve practical problems more rationally than by blind trial and error. That social revolution—the beginnings of agriculture and urbanization—caused a shift in problematics and in methodics, and this in turn gave us the type of knowledge we are proud (and sometimes ashamed) of. And, of course, some of the outcomes of such intellectual endeavors have in turn elicited profound changes in our life styles—not always for the better.

Problems are the root and the fruit of original research, be it in science, technology, or the humanities. Therefore we should correct the neglect of the very concept of a problem in the philosophy of science. More research on the logic, semantics, and heuristics of problems should be able to help us work better at finding and solving problems. In particular, it should help us avoid barking up the wrong tree and devoting our talent to pseudoproblems (such as trying to reduce social science to psychology or to biology) and *cul de sac* problems, i.e. miniproblems whose solution would make no noticeable difference to the state of knowledge or of society.

The specialist may be trusted to spot wrong solutions, but spotting wrong problems takes more than professional competence, particularly when an entire army of knights has been tilting at windmills for some time. In such cases there is a (bad) model to be imitated and even a vested interest in persisting in the effort. (The quixotic attempts to build logics of analogy and of induction, to reduce all philosophical notions to those of probability or of information, and the exact but barren investigations in subjective probability, modal logics, and possible worlds, come to mind.) As Ackoff (1974, p. 8) puts it wisely, "We fail more often because we solve the wrong problem than because we get the wrong solution to the right problem".

A touch of epistemology might also help spot and avoid trivial problems, i.e. problems which, though well formulated, are unlikely to add significantly to human knowledge. All sciences, particularly though not exclusively the less advanced ones, are littered with trivial research, the only functions of which are to allow some individuals to make a living, and to render the volume of the literature unmanageable. Think of the human and material resources that have gone into confirming the well-known platitudes that talent depends on both genetic factors and opportunities, that groups composed of competent people perform better than bunches of incompetent people, that persons with low self-esteem are reluctant to participate in group work, that group discussions are dominated by high ability or highly vocal individuals, and so on. No wonder the announcement of such trivialities is usually greeted with the sneering question 'So what?', or (in Newyorkese) 'So what else is noo?'.

In conclusion, valuable inquiry is triggered by good problems. How does one get new problems? By reflecting critically on old problems and their solutions, as well as on new situations. And how does one get ideas to solve the new problems? By struggling with them. Problems, in sum, are the very heart of inquiry.

CHAPTER 8

CONJECTURING

Solving problems, whether practical, cognitive or moral, involves conjecturing: that this fruit is edible and that animal dangerous; that these rains announce a cold spell, and that stranger is friendly; that this stone may be suitable for fashioning an axe, and those twigs for kindling a fire; that this action may benefit my kin and that one hurt them—and so on and so forth. Every problem demands making some conjecture or other, and every conjecture poses the further problem of finding out whether it is adequate (true, efficient, or good).

We seldom face experience without some preconception and anticipation, and we never undertake scientific experimentation or technological design without some hypotheses. It is not that we are perfectly rational beings, nor that we abstain from perceiving or doing until we have formed a true theory or a suitable plan, nor that every datum is preceded by some careful cognition, but that perceiving, thinking and doing go often hand in hand. To be sure we are often taken by surprise, unprepared to react to or understand what happens to us. But only those who know and expect something can be surprised, and only those who make some conjectures about surprising events, and care to check such conjectures, can hope to survive, or at least to subsist as rational beings.

1. FROM PRECONCEPTION TO HYPOTHESIS

1.1. *Psychobiology of Conjecturing*

We all know that the animals capable of learning can learn to expect certain events to follow others, and to perform certain actions after certain events occur, or in order to attain certain goals. But how do they learn: by reinforcement of the adequate expectations and actions, or by forming and trying out alternative hypotheses? Behaviorism gives the former answer, and cognitivism the latter. (Note, by the way, that this disjunctive problem contains the hypotheses we wish to discuss.) Perhaps both schools are right: maybe the two learning mechanisms operate in the higher animals, whereas the lower ones learn only, if at all, by reinforcement. But, since this chapter happens to be about the nature of hypotheses and their role in problem solving, in this case we are likely to learn more from cognitive psychology than from behaviorism.

Classical—i.e. mentalistic and introspective—psychology had paid much attention to thinking and, in particular, to hypothesis formation, though usually without employing the experimental method. (See Claparède (1934) for an excellent detailed review.) In particular, Gestalt psychology had emphasized the role of hypothesis in problem solving among primates, but it had ignored the question of testing. The animal faced with a problem was said to start by making a few haphazard trials, then engage in serious thinking until struck by a clap of insight, upon which he acted in the correct way. There is some truth in this picture but it is incomplete and inaccurate. Preliminary exploration is often systematic (because guided by experience, by cues or by clues) rather than random. And hypotheses are tested (in imagination or empirically) no sooner they are formed. Moreover the outcome of such tests often suggests new hypotheses or poses new problems.

The breakthrough in the experimental study of the role of hypothesis in problem solving was inspired by Lashley (1929) who, in an influential book, suggested that learning proceeds by making hypotheses and putting them to the test. Krechevsky (1932) and Tolman and Krechevsky (1933) took up this idea and tested it in rats. They found that the rat does not behave haphazardly during the early stages of a problem-solving process but proceeds quite methodically, "attempting various solutions and giving them up when they fail, until he hits finally upon the 'correct' one" (Krechevsky, 1932). This work was severely attacked by the behaviorists, in particular K. Spence, and so the incipient American branch of cognitive psychology went underground. (It never ceased to be in the foreground of European psychology.)

The hypothesis that the higher vertebrates learn by making hypotheses and testing them resurfaced in America with *A Study of Thinking* by Bruner, Goodnow and Austin (1956). It is now being investigated vigorously both in the laboratory and mathematically. (Cf. Restle, 1962; Levine, 1966, 1974; Mayer, 1977.) One finding of this research is that human learners are not passive: they do not respond always in the same case to a given stimulus, but their response depends upon their experience, expectations, etc. Another is that the correct response is not strengthened gradually by reinforcement: in some learning tasks the subject can learn at a single trial. Both results, known or suspected by nonbehaviorist psychology, refuted behaviorism.

Restle (1962) has interpreted these experiments in the following way. At the outset of a learning task (discrimination learning, maze learning, or concept formation) the subject has a universe of hypotheses or strategies. He samples them first at random, and acts accordingly. If he hits on the correct hypothesis or strategy, he sticks to it without making any further errors. Otherwise he tries again by resampling. So he may choose the just rejected hypothesis with the same probability as any other one—a rather implausible assumption. (The only rationale for it seems to be that it allows its author to model the process on that of a lottery with replacement, and so with constant probability for each strategy or hypothesis.)

This model seems unsatisfactory if only because it contains the zero-memory hypothesis just commented upon. But there is more. If a problem is soluble at all, then either there are methods for tackling it or there are none. If there are, then the subject may know some of them or he may not know any. If he does, then he is likely to try first the simplest, or the one he remembers best. And if he does not know of any such method he may give up or give it a try. If the latter, he is likely to proceed by groping (*tâtonnement*) but not wholly in the dark: one is always guided by certain clues, and one can always exert one's imagination.

That hypothesis formation is seldom haphazard is suggested by observations and experiments on the way children and adults solve qualitative combinatorial problems. Take for instance anagrams, and in particular the 5 letter word 'ilrta', meaningless in English. There are 119 variations of this string of letters but only a few of them, such as 'trail' and 'trial', belong to the English vocabulary and therefore qualify as solutions. Experiment shows that, typically, subjects do not try all the 119 permutations but begin with the combinations that have the highest frequencies, e.g. 'tr' rather 'rt'. (The strength of such clues is such, that subjects find it usually difficult to break the letter pairs that occur frequently, so a problem word such as 'beach' is harder to crack than its anagram 'hbcae'.) In any case, the time it takes most subjects to solve such problems varies typically between 10 seconds and 2 minutes, and is therefore too short to allow for the examination of all the alternatives. (See, e.g. Mayer, 1977.)

So, even in the absence of methods one usually employs some clues, not always explicit, i.e. knowledge—explicit or tacit—of certain regularities that he has learned before. That is, hypotheses, even when they seem to come by sudden illumination, do not jump out of nothing but are somehow generated from available knowledge. Exactly how they are formed we do not know yet, but it is likely that thinking up a new hypothesis is identical with the activation of a new psychon. It would also seem that there are several different modes of generation. Let us consider quickly a few of them.

To begin with there is induction from observed cases, either from very many or from just a few or even one. Thus it usually takes a young dog a single disagreeable experience with fire to form the generalization that all fires burn. Because of the universality of induction among the higher vertebrates, it cannot be the mark of science—*pace* the opinion of most inductivist philosophers. What is a (though not the) mark of science is the control or test of generalizations, inductive or not, by means of observation or experiment, as well as the attempt to explain them—e.g. to understand why fires burn. Without such tests, i.e. without going beyond the empirical sources of our hypotheses, we are likely to accumulate false beliefs, such as the time-honored ones that every existent fulfils some function in a well designed order; that all celestial bodies revolve around our planet; that every comet announces some major catastrophe; that all societies are stratified; that all conquered or colonized peoples are inferior; that all humans believe in deities; and that all knowledge comes from the senses. After all, every one of these superstitions has a good empirical basis.

At other times we form hypotheses by noting associations. Thus if we know that A and B often occur together, or one after the other, we are likely to conjecture that A and B are somehow correlated or even functionally related. (This requires the prior nontrivial isolation of A and B from the jumble of phenomena, or even the hypothesizing of their existence.) Unless we are engaged in scientific or technological research, we are likely to care only for the joint (or successive) occurrence of A and B, disregarding the three remaining cases, which are just as important, namely A and not-B, not-A and B, and not-A and not-B. For example, even experienced nurses will "see" nonexisting correlations between disease and symptom for disregarding such negative cases; and, in general, "adult subjects with no statistical training apparently have no adequate conception of correlation" (Smedslund, 1963, p. 165). The fallacy of nonexisting association is of course at the root of many superstitions, such as the beliefs in magic, astrology, and miraculous cures.

At other times we form hypotheses on the strength of similarities, real or imaginary. Thus Faraday invented the concept of electromagnetic field by analogy with the concept of an elastic body; and Darwin drew inspiration from his readings about economic competition and overpopulation. At still other times we form hypotheses with the help of general principles. Thus if we note that the total energy of a system has decreased or increased, we use the principle of conservation of energy to conjecture that the system is not closed, so that there has been an energy leak.

However, the deepest and therefore most important hypotheses are not suggested by recurrent phenomena, repeated associations, or real analogies, but they are newly invented. The reason is that, by definition, a deep hypothesis concerns facts that are not accessible to direct observation. The phenomenal world is complex and messy. A meticulous recording of everything we perceive is unilluminating because of excessive detail. To understand what we perceive we must imagine imperceptible things or connections, or analyze in imagination what perception presents as a solid block.

Thus Harvey, who had at his fingertips just as many anatomical data as his predecessors, was the first to conjecture that the heart, the arteries and the veins form a system of closed circuits. Part of this conjecture was the hypothesis that there are capillaries, invisible to the naked eye, that join the ends of the arteries to the beginnings of the veins. This hypothesis was confirmed, with the help of the newly invented microscope, only after Harvey's death. Likewise Maxwell, guided by the general hypothesis that all electric currents are closed, postulated the existence of a displacement current between the plates of a discharging condenser. This hypothesis was confirmed after his death. And Ramón y Cajal, using Golgi's staining technique, showed that every region of the brain is composed of neurons. Although his preparations exhibited only discrete cells, he conjectured that the brain forms a system, and this hypothesis was confirmed only half a century later with the discovery of synaptic transmission. In all three cases the initial data had been insufficient even to describe what happened. In all three cases the hypotheses turned out not only to be true but also tremendously fertile. But although deep, audacious and path-breaking, all three conjectures were initially just explicit and testable educated guesses. In this regard they were no different from the thousands of hypotheses, of varying grades, that every active scientist, technologist, humanist or professional frames in the course of a year.

1.2. *Hypothesis*

In mathematics the word 'hypothesis' designates an assumption such as a datum of a problem. For example, in proving a theorem about right angle triangles we may, at a certain point, need to remind ourselves that, *by* *hypothesis*, the triangles in question have a right angle. Tentative statements, such as candidates to theorems, are called 'conjectures' in mathematics. We shall be concerned throughout with conjectures.

We make guesses or conjectures all the time, in ordinary life as well as in the various sciences, technologies, arts, and professional activities. However, not all of our conjectures deserve being called 'hypotheses'. Only the *educated guesses* that are *formulated explicitly* and are *in need of testing* qualify as hypotheses. The formulation must be explicit but need not be propositional: the design of an artifact, a historical reconstruction, the reconstruction of a lost original, and the program of a course of action qualify as hypotheses. See Figure 8.1.

We have employed the expression 'educated guess' to designate a guess that, far from being wild, is compatible with some background knowledge. For example, suppose we are asked to guess the number of children in Peanutia, a Third World country with one million people. A wild guess is an arbitrary number between 0 and 1,000,000. An educated guess is this: since in most Third World countries children constitute half the population, Peanutia has about 500,000 children. This guess is educated and it can be put to the test by looking up the latest census figures: it is a testable hypothesis. The guesses of all experts are of the same kind and are formed in the same way: by combining bits of specific information (e.g. the total population of a certain Third World country) with generalizations (e.g. that in Third World nations persons up to 15 years old constitute half the population).

Some of our hypotheses concern observed or observable facts, like the conjectures we make while driving, about the congestion of traffic ahead, or the coming rainfall, or the possible outcome of a test (e.g. an experiment), or the performance of an as yet untried artifact. Other conjectures are about unobserved and perhaps unobservable facts, like those about other people's intentions we make while driving, or the behavior of our relatives while they are not being observed, or the efficiency of a new form of organization, or the nonphenomenal properties of things of any kinds.

The hypotheses concerning as yet unobserved entities or properties must be conceived, of course, before the corresponding direct or indirect observations can be performed. At the time of conceiving such hypotheses there may be data, but all they do is to pose the problem of explaining them and constraining the possible hypotheses. Moreover the hypotheses are needed in order to design observations aiming at showing the existence or nonexistence of such entities or properties. Recall some outstanding

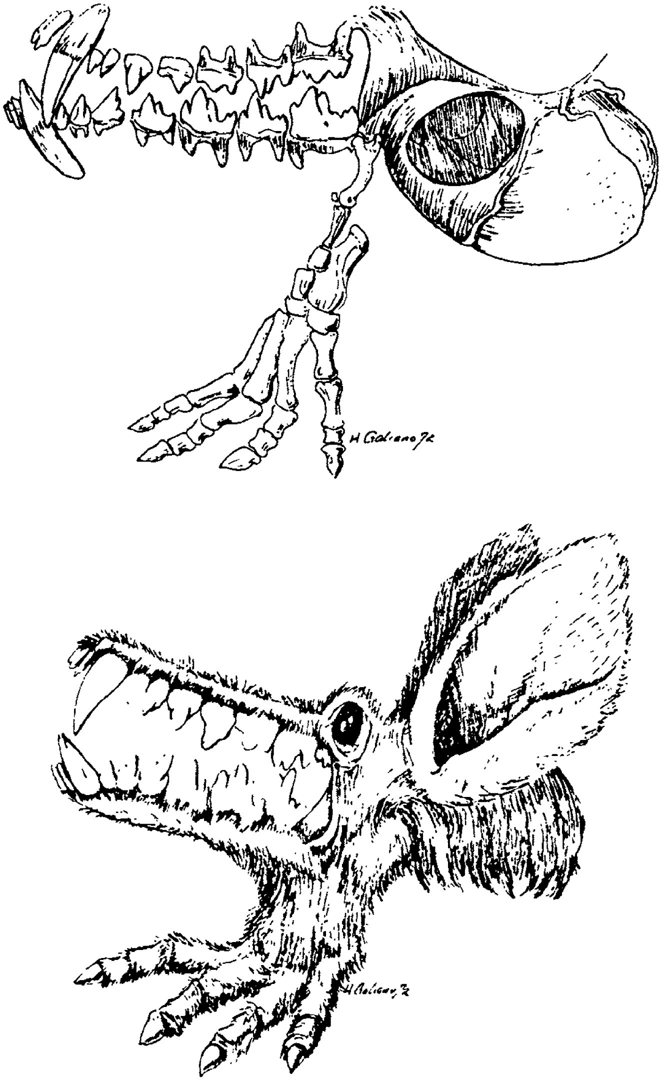


Fig. 8.1. Hypothetical reconstruction of the past: the case of fossil mammals according to McKenna (1976, pp. 246–7). (*a*) Strict adherence to the data (fossil bones) would lead us to believe, as the late A.S. Romer used to say in jest, that the extinct mammals were merely teeth that lived, gave birth directly to more teeth, and died. (*b*) We know better: the early mammals had also a foot, an auditory apparatus, and fur.

examples of this kind of hypothesis: atoms were hypothesized twenty-three centuries before their existence could be established experimentally; genes and antibodies were postulated half a century before being observed and identified chemically; nuclear, interatomic and intermolecular forces are hypothesized in order to explain the outcome of scattering experiments, the main function of which is to furnish some indications about those forces.

Some of the unobserved facts we make hypotheses about are in principle observable and, with ingenuity and luck, are eventually observed. Others are unobservable *in principle*—at least according to our present knowledge. A clear case in point is that of historical hypotheses, i.e. hypotheses about the past of the universe or of any part of it. All such hypotheses are about alleged facts that, not existing any longer, are unobservable in principle. To be sure, some such facts are of the repetitive kind and so we can use our knowledge about current facts of the same kind. For example, the emission and absorption of light can be assumed to "obey" now the same laws it "obeyed" a thousand million years ago; and we can assume that the earliest hominids had most if not all of our own basic needs.

But other facts are unique or unrepeatable. Hence if past and unobserved they must be reconstructed hypothetically on the strength of whatever traces they may have left, and of some regularities. For example, the feeding habits of animals belonging to extinct species can be reconstructed in either of the following ways. One is to analyze the undigested remains of the excreta, which are rather exceptional findings. If this method cannot be used for lack of data, the palaeontologist attempts to reconstruct the physiology of the animal on the basis of its fossil remains—an exciting and chancy exercise. A third, no less fallible way, is to extrapolate back from the known feeding habits of living relatives. The best procedure would of course be to combine all three, but this is seldom possible. And in any event each of the three methods involves making hypotheses. In general, the shorter on empirical evidence the longer on speculation, the longer on evidence the longer on well-founded hypothesis, and the longer on the latter the longer on new discoveries or inventions. To abstain from speculating altogether is to condemn oneself to living in the present without understanding it. Not speculation in itself but only wild, i.e. groundless and untestable, speculation is to be shunned. Let sound speculation flourish.

Every inquiry, even the simplest data gathering operation, involves some hypotheses about the object of study as well as on the manner of studying it. (The former are substantive, the latter methodological hypotheses.) For example, in going about their data gathering, anthropologists and field linguists have usually assumed that the uneducated elders of the tribe or the village were the repositories of tradition and language in its purest form, before being corrupted by the radio, tourists, or visiting scientists. In this way they collected many data that were not representative of the population as a whole and even, in some cases, histories deliberately made up to please or fool the scientists. That such mishaps are difficult to avoid is beside the point. The point is that data, whether in science, technology, the humanities, or professional life, are always sought in the light of some substantive and methodological hypotheses: before rushing to make observations or experiments we must choose the kind of data we want and must decide how best to obtain them. What to do with the data once collected is another story.

According to empiricism the task of the researcher is finished once he has got his data. At most he may summarize and cautiously generalize the information thus obtained, i.e. he may formulate low level hypotheses. (A hypothesis may be said to be of the *low level* kind if it contains no substantive or technical concepts other than those occurring in the data it covers. Data-fitting curves are of this kind.) No doubt such a task is to be performed, if only because the low level hypotheses are raw material for the theorist. See Figure 8.2. But some of us want not just to know what is the case but also to understand, and this calls for inventing further hypotheses—explanatory hypotheses. In short, the process is not from data to hypotheses (the positivist schema) but from problem to hypotheses, and from these either to data (in the case of empirical research) or to further hypotheses (in the case of theoretical research), and from either to control or test—and then back to the original problem or forward to yet another problem, perhaps one generated by either the hypothesis itself or its test.

Think of any of the research processes that culminated in some of the most interesting findings of our century—e.g. the quantum theory of atoms, which is not a data package but a high level construct containing no

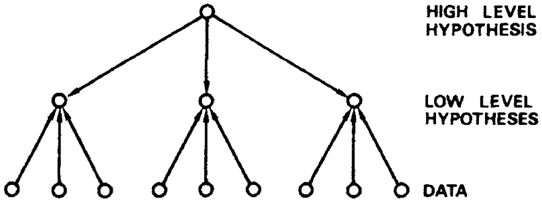

Fig. 8.2. High level hypotheses colligate and entail low level hypotheses, which in turn summarize and generalize (but do not entail) data.

data proper. The motivation for building it was the failure of classical physics to explain some facts known of old as well as some newly discovered facts. There was nothing to induce from: induction came only at the end, when evaluating the theory in the light of experimental results. Or think of the many hypotheses involved in any model of the economy of a whole nation, such as an econometric model of the US economy. Or of the many hypotheses involved in any long term development plan—or, for that matter, in any plan to turn back the social and economic clock. Or, finally, think of the history of television and the host of hypotheses of all levels, including some taken from electrodynamics and others from electron physics, involved in it.

Are there any rules or methods for conceiving hypotheses? A number of outstanding thinkers, among them Leibniz, have claimed that they had invented, or could invent, an *ars inveniendi* or logic of invention and discovery. The idea was to invent a handful of precise and comparatively simple recipes wherewith anybody could discover truths regardless of his background, talent, and motivation. Of course nobody did in fact exhibit any such universal rules, and the project died out. A few optimistic philosophers (notably Hanson, 1958) tried to revive it in our century but, predictably, they too failed. The project of inventing an *ars inveniendi* is chimaerical because originality consists in breaking new paths, not in following existing ones. It would be far less wrong-headed to investigate which chemicals, and at what concentrations, favor or inhibit original conjecturing. And it is a legitimate problem for sociologists and historians to find out what types of social condition stimulate or inhibit conjecturing. (Cultural freedom, though necessary, is insufficient. Affluence, though helpful, is neither necessary nor sufficient. A tradition of learning is ambivalent. And a philosophy contemptuous of hypotheses is inimical.)

However, there are a few methods for generating hypotheses from data. Any interpolation formula, allowing one to construct a continuous curve (a polynomial) out of a finite number of data, is such a technique. The technique for calculating linear regressions is another. These and other techniques can be incorporated into computer programs. In fact computers can be programmed to generate hypotheses of the following kinds: "A is associated with B", "A increases with B", "A decreases with B", and "C makes A and B correlated" (Hájek and Hávranek, 1978). More advanced programs, particularly DENDRAL, are employed in organic chemistry to form the plausible structure diagrams of molecules on the basis of their composition and mass spectra, the valence of their component atoms, and a few other data and hypotheses (Lederberg and Feigenbaum, 1968). In short, it is possible to mechanize induction.

All such algorithms are of great practical value to process huge masses of data, as is the case in statistics, chemistry, medicine, and some other fields. However, it must be kept in mind that the resulting hypotheses are all *low level* ones and therefore of no great theoretical interest. In fact the hypotheses generated by algorithms out of data (*a*) colligate data (to use the term introduced by Whewell (1847)); (*b*) involve only substantive concepts occurring in the data (e.g. those of atom and valence in chemistry), and (*c*) are mathematically extremely simple-minded.

The generation of powerful hypotheses, such as differential and integral equations, is beyond the reach of any algorithm or machine program. Even simple law statements such as Snell's law of refraction cannot be generated from a bunch of data. What one can do with a computer is to *check* whether a given high level hypothesis fits a certain data base. In sum, computers can help process data and generate low level hypotheses, as well as find out how well or poorly the latter fit the data. But they cannot invent any high level hypotheses because the latter involve, by definition, concepts that fail to occur in the data.

We do not know of any rules or methods for generating high level hypotheses such as the hypothesis of natural selection, economic determinism, or the Schrödinger equation. We just grope for high level hypotheses, helped or hindered by induction or analogy, by general principles or mathematical forms, and always spurred by imagination, a knack for discerning or guessing patterns, and the philosophical conviction that there *are* patterns to be uncovered. All of the high level hypotheses are invented in an unruly way and perhaps also unconsciously. Only their precise formulation and checking must be methodical and fully conscious.

Philosophers, in sum, are no longer interested in the chimaerical project of setting up a logic of discovery or of invention. They work, on the other hand, on such problems as: (*a*) defining the very concept of a hypothesis, (*b*) classing hypotheses (e.g. into empirical and theoretical, or low level and high level, substantive and methodological, etc.); (*c*) unearthing the clues that led or misled to the formation of some hypotheses of historical interest; (*d*) establishing the conditions a hypothesis should fulfil in order to deserve being examined theoretically or empirically; (*e*) establishing the conditions for concluding that a hypothesis has been satisfactorily confirmed. These are genuine problems, and open ones for the most part. (Because of the empiricist tradition in epistemology they are often lumped under the misnomer *Induction.*) We shall address some of them in this book.

2. SCOPE AND DEPTH

2.1. *Scope*

Hypotheses come in all scopes or extensions, and the real scope of a hypothesis is not always apparent but must be dug out by logical analysis. We distinguish the following kinds of hypothesis with regard to scope:

1. *Singular* hypotheses, such as "This machine should work", and "That social program should decrease unemployment".

2. *Particular*
   2.1. *Indefinite* particular hypotheses, such as "There are black holes", which specify neither place nor time and are therefore hard to refute.
   2.2. *Definite* particular hypotheses, like "There are decision-making modules in the frontal lobes of all normal higher vertebrates".

3. *General*
   3.1. *Bounded universal* hypotheses, such as "All Renaissance intellectuals were generalists", that are restricted to certain places or times.
   3.2. *Unbounded universal* hypotheses, such as the laws of physics.

Scope is no ambiguous indicator of importance. Thus the hypothesis that such and such conflict was a trade war may be more important to us, who live in the shade of world wars, than many a generalization of mirmicology or of malacology. Besides, some hypotheses are singular in one respect but universal in others. For example, the astronomical and geophysical laws concerning our planet are referentially singular but they are universal with respect to time. For example, "The Earth spins" abbreviates "For all times since its formation the Earth spins". Likewise every statistical correlation, e.g. between the height and weight of persons, is a universal statement. Indeed, "Variables A and B are strongly correlated" means that, for every value of A, the corresponding value(s) of B lie close to the linear regression line.

Nor is scope, or quantifier type, a precise indicator of degree of generality: logic is too coarse a tool of analysis as compared with mathematics. For example, "For all $x, f(x) = 0$" is a special case of "For all $x, f(x) = a$", which in turn is subsumed under "For all $x, f(x) = a + bx$", and so on. Likewise rest is a special case of motion, uniform motion (or stationary state) a more general one, and uniform acceleration still another, even more general kind. Neither of the above generalizations is inductive, for neither consists in jumping from singulars to universals. They are generalizations from species to genera, from these to families, and so on. (Recall Ch. 6, Section 2.2.) Moreover, as a matter of historical record some of the higher order generalities were conjectured before the special cases were investigated.

Empiricists have always cautioned against the sin of overgeneralization, and have advised us to stick to singulars, the only genuine existents. There is no need for such warnings, since empirical tests will correct any excesses. Tests will also correct the dual mistake of undergeneralization, by showing that what was initially thought to hold only for a given set of facts holds also for a superset of it. (A notable recent case was quantum mechanics, originally conceived for atoms only, but later generalized to molecules, atomic nuclei, and even certain macrosystems such as superconductors.) Of the two complementary mistakes, undergeneralization is more dangerous than its dual because it may consist in not making any generalizations at all, or in stopping at low level generalizations. After all, a high level general hypothesis is better than none, for it stimulates thinking and experimenting—and it is fun.

Generality is related to inferential power, or the capacity a proposition may have of generating further propositions with the help of some formal tools. Actually even the most modest singular proposition, such as a datum, may be said to have an infinite deductive power, for it entails infinitely many conditionals where it occurs as a consequent. (I.e., e entails $h \Rightarrow e$, with h arbitrary. In fact, suppose the inference invalid, i.e. $h \Rightarrow e$ false. This holds only if h is true and e false—which contradicts the hypothesis that e is true.) Such profligacy of singulars is uselesses because, by entailing anything, they generate nothing in particular. (Inductivists, take note.) Genuine deductive power consists in the possibility of specification, in particular instantiation.

We distinguish two genera of hypothesis with regard to specifiability: the unspecifiable and the specifiable ones. Singular propositions, such as "b is an F", and particular propositions, such as "Some A's are B's" (or even "Most A's are B's"), do not entail anything definite. Likewise the outcomes of statistical analyses, such as "f percent of A's are B's", and "The standard deviation of the F distribution is such and such", entail nothing. In general statistical statements, unlike general probability statements (e.g. on probability distributions), are deductively barren. They are terminals of inquiry and, at most, they pose the problem of setting up models for explaining them.

We distinguish two species of specifiable hypotheses: immediately and conditionally specifiable. An *immediately specifiable hypothesis* is one from which singular hypotheses can be derived by assigning definite values to variables. The empirical generalizations and the lowest level theorems of factual theories comply with this condition. For example, if a function f solves a certain ordinary differential equation, it follows that its value at point b is $f(b)$. (That this value may be difficult to compute is beside the point.) A more interesting example: the basic equations of a fundamental theory, such as classical dynamics or classical electromagnetism, are specifiable to species and to individuals by specifying the functions and parameters occurring in them—e.g. by specifying the force function, the mass value and the initial conditions in Newton's law of motion, or the four-current and the boundary values in Maxwell's laws.

A *conditionally specifiable hypothesis* is one that can be "applied" (made to refer to) individual cases, or subordinate species, upon suitable formal or semantical transformations. For instance, differential and integral equations must be solved and assigned factual interpretations before they can be so "applied". Mathematics takes care of the indicated formal transformation, but it is the responsibility of the scientist or technologist to "read" the resulting formulas in terms of concrete things, their properties, and changes in the latter. That is, the mathematical formula must be adjoined meaning assumptions or correspondence rules. (Cf. Vol. 2, Ch. 7.)

Some hypotheses are so extremely general that, in conjunction with particular or even singular bits of information, they entail further general—though somewhat less general—hypotheses. For example, if a given organic molecule consists of subsystems A and B, it can be hypothesized that A and B are the precursors of the molecule (i.e. have preexisted it), on the strength of the general postulate that every complex system has arisen by the assembly of its components. This is so general a hypothesis that it belongs in the intersection of science, technology, and philosophy (Vol. 4, Ch. 6).

Scientific, technological and humanistic research are conducted with the help or hindrance of a number of philosophical hypotheses. We mentioned a few such hypotheses of an epistemological kind in the Introduction, Section 6, as well as some hypotheses of the ontological kind in Vol. 3, Introduction. These philosophical hypotheses do not occur among the findings of scientific, technological or humanistic research, but they guide research and are controlled by it. One such hypothesis is that logic and mathematics have no factual content and therefore (*a*) can be used in any epistemic field and (*b*) are not testable by any empirical procedures—i.e. they are a priori. Another is that we can get to know more than appearances, i.e. that it is legitimate, nay mandatory, to frame and use transempirical concepts and hypotheses. A third, that the object of research is distinguishable from the knowing subject. (To be sure, the latter may influence the former, but no such influence would be possible if they were indistinguishable, i.e. one rather than two.)

Every one of these and other philosophical hypotheses is presupposed by modern research, but this does not entail that every epistemic field has a permanent philosophical basis, or that philosophy can be the ultimate arbiter. What it does entail is that there is no separation between philosophy and the other epistemic fields; consequently that neither of them can advance without the other's support and criticism. Philosophers are not equipped to approve or question any specific hypotheses in fields other than their own—unless of course they happen to be conversant with them—but they are certainly competent to approve or question the philosophical hypotheses presupposed by such specific hypotheses. Although such philosophical presuppositions of research provide no ultimate foundation, they do constitute a provisional basis to be further analyzed, systematized, supported, or corrected. They are true to the extent that they facilitate the search for truth, barren if they neither lead nor mislead, and false if they hinder such search in any way.

2.2. *Depth*

Scope is only one of the dimensions that determine the size of a hypothesis: the other is depth. We stipulate to call a hypothesis *deep* only when it contains transempirical concepts, and otherwise *superficial*. For example, the hypothesis that syphilis is only a skin disease is literally skin-deep. It was held for thousands of years and it sheltered a number of fantastic conjectures about the origin of syphilis—e.g. that it was ordained by the stars, and that it was a divine punishment for the sin of fornication. In the wake of the microbiological revolution initiated by Pasteur, the programmatic hypothesis was formulated that syphilis was caused by a microbe. Methodical investigation into this deep (transempirical) hypothesis proved successful: in 1905 *Spirocheta pallida* was discovered and incriminated. (Cf. Fleck, 1935.) In turn, this finding posed the technological problem of getting rid of the microbe—a problem solved only with the advent of antibiotics half a century later.

Something similar is happening nowadays with regard to cancer. Surgical practice and observation have produced plenty of accurate descriptions of the outward appearance and location of cancerous tumours; clinical observation has yielded many data on the symptoms of cancer; and histological observation has completed the picture. But neither of these procedures could possibly tell us what the mechanism of cell proliferation can be, and consequently neither of them can give us a clue to the prevention or cure of cancer. On the other hand cell biologists, molecular biologists and virologists are on the right track and are learning more and more about such mechanism. The ultimate goal is a detailed and precise (if possible mathematical) model of cell proliferation—an explanatory, not just a descriptive one. But we will not get such a system of deep hypotheses if we continue to believe that knowledge can be gained only through observation or practice; if researchers continue to adhere to the empiricist epistemology, which shuns transempirical concepts and therefore deep hypotheses; and if most science administrators continue to look upon the problem as one in medicine rather than in biology.

According to our definition, a hypothesis qualifies as deep if it contains at least one transempirical concept—aside of course from the logical or mathematical concepts occurring in it. Now, we must reckon with several degrees of depth. Thus a black box model of a system, i.e. one that ignores its internal composition and structure, is superficial, for it represents only the observable inputs and outputs. If we allow for internal states of the box, i.e. build a grey box, our representation of the system becomes somewhat deeper. Still, this depth is not impressive as long as the internal states are not identified as states of the internal mechanism of the box.

For example, the simplest model of a system is the vending machine with just two internal states, the ground state and the excited state: Figure 8.3. In the absence of external stimuli the machine stays in the ground state, i.e. it lacks initiative. (When it does exhibit initiative and starts delivering goods without being stimulated, it is judged to be out of kilter.) When a stimulus of a certain kind, e.g. a coin, impinges on the machine, the latter jumps to the excited state, produces a response of a certain kind (e.g. delivers a candy bar), and returns to its ground state. Such a system can be realized in many ways, i.e. it is compatible with a whole family of internal mechanisms—mechanical, electrical, chemical, etc.

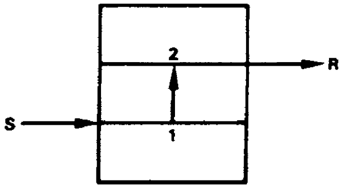

Fig. 8.3. A two state grey box model of a system. When stimulus S impinges on the system, the latter jumps from state 1 to state 2, produces response R, and then decays back to state 1. If the machine is probabilistic, it responds to the stimulus with a given probability p, so it steals dimes a fraction $1-p$ of the times it is stimulated. A simple mathematical representation of such probabilistic machine is the matrix equation $R = MS$, where $M = \begin{Vmatrix} 0 & p \\ 1 & 0 \end{Vmatrix}$ and $S = \begin{Vmatrix} 1 \\ 0 \end{Vmatrix}$, whence $R = \begin{Vmatrix} p \\ 0 \end{Vmatrix}$, with $0 < p \leq 1$.

The consumer may not mind the kind of mechanism as long as it is functional. But of course scientists and engineers are keen on discovering or designing the mechanisms of the systems they study, for they wish to understand or master them. In particular the neuropsychologist wishes to understand the neural mechanisms of cognition: he cannot remain satisfied with the "cognitivist" or "functionalist" dogma that only the "software" or program matters, the "hardware" or neural stuff being irrelevant. If a philosopher insists on remaining ignorant of such mechanism, it is his privilege. But he has no right to press for a commitment to such ignorance as the right strategy for investigating the mind. (More in Vol. 6.)

The search for, and description of, mechanisms involves *mechanismic* or *dynamical* hypotheses, i.e. deep conjectures about mechanisms of some kind—mechanical or electrical, chemical or cellular, organismic or ecological, economic or cultural. The hypotheses that gas pressure is due to molecular impacts, and that extreme class differences cause discontent, are well known examples of mechanismic conjectures. Nonmechanismic hypotheses, whether or not they contain transempirical concepts, are called *phenomenological*, *kinematical*, or *black box* conjectures. The thermodynamical relations between pressure, volume, and temperature, and the stimulus-response hypotheses of behavioristic learning theory, are typical examples of phenomenological conjectures.

Kinematical or black box hypotheses are easier to frame and test than their dynamical rivals. Moreover kinematical hypotheses contain adjustable parameters and can therefore be made to fit the data more perfectly than the corresponding dynamical hypotheses. It is always easier to describe a state or a change of state than to explain how it comes about. However, we need hypotheses of both kinds for, after all, a description of facts must be available before we can proceed to explain it. Thus phenomenological hypotheses, even if they fit accurately the known data, pose the task of framing mechanismic hypotheses capable of explaining the former. We must welcome black box hypotheses, though not hail them as the culmination of the research process, and we must resist the black box philosophy that shuns mechanismic hypotheses (Bunge, 1964).

In the history of science it has been common for phenomenological and mechanismic hypotheses to conflict over a domain of facts. More often than not mechanismic hypotheses have either replaced or supplemented their phenomenological rivals. Recall the following cases: (*a*) the hypotheses about electromagnetic fields eventually displaced those of action at a distance (or direct inter-particle interaction); (*b*) chemical kinetics, which centers around equations for the rate at which chemical reactions proceed, are supplemented by hypotheses concerning reaction mechanisms (intermediate reactions), which are in turn explained by quantum chemistry in terms of forces and collisions; (*c*) the hypothesis that biopopulations evolve has been supplemented by the hypothesis that evolution proceeds by spontaneous genetic changes, natural selection, geographical isolation, etc.; (*d*) the descriptive generalizations of mentalistic and behavioristic psychology are supplemented or replaced by neuropsychological hypotheses; (*e*) the matrices of social mobility theory are supplemented by hypotheses about the economic, cultural and political "forces" causing job and status drifts.

Needless to say, a mechanismic or dynamical hypothesis is supposed to describe with precision some mechanism or other, not just state that there is, or must be, a mechanism. The latter would be a *programmatic* hypothesis inspiring the search for precise mechanismic hypotheses. Thus Maxwell's equations for the void describe in detail the mechanism of propagation of an electromagnetic field. On the other hand, when Chomsky (1980) and his school claim that the human mind contains innate mechanisms for the generation of grammatical sentences, they state only a programmatic hypothesis, for they do not even sketch such alleged mechanisms. And, since the conjecture of the inborn generative grammar is imprecise, almost any data can be construed as confirming it. Moreover, in a psychobiological perspective the mind cannot contain any mechanisms, for the mind is only a collection of neural processes (Vol. 4, Ch. 4). There are on the other hand neurophysiological mechanisms, in particular mechanisms of formation and dissolution of plastic neural systems. In other words, the psychological mechanisms are neurophysiological. No matter, no mechanism.

What holds for psychological mechanisms holds also for social ones: they are all mechanisms of concrete things—in this case living individuals and functional social systems. For example, the hypothesis that a high rate of interest is a cause of inflation, not a deterrent to it, is true but superficial, for it does not indicate any mechanism. A more complete story, and therefore a better guide to action, is contained in the hypothesis that a high rate of interest decreases the rate of borrowing, which in turn diminishes spending, which decreases production and trade, which decreases employment, which in turn decreases spending, and so on. Incidentally, the central hypothesis of monetarism, namely that the essence of an economy is the flow of money, and therefore controlling money is the most effective way of controlling the economy, is a typically superficial (and false) hypothesis: producers and consumers, together with resources and commodities, not the means of exchange, compose an economy. (More on this in Vol. 6.)

We have declared our preference for mechanismic or dynamical hypotheses over phenomenological or kinematical ones. This preference for depth, though justified, is far from universal. In fact most people prefer black box hypotheses because they are easier to frame, fit to the data, and test. In addition, black box hypotheses have been recommended on philosophical grounds. One of them is conventionalism: If all our assumptions are mere conventions and none represents reality, why not choose the simplest, in particular the kinematical ones? Another is empiricism: If all we can get to know are appearances, why conjecture hidden mechanisms instead of remaining content with hypotheses relating the observable inputs and outputs?

Conventionalism as well as empiricism include then simplicism, or the methodological rule that recommends preferring the simplest of all hypotheses compatible with the data. There are two main variants of simplicism: moderate and radical. The former is Ockham's razor, or the principle according to which "Plurality [of entities, properties, causes, etc.] is not be be assumed without necessity". This variant of simplicism is moderate, for it discourages the invention of fictions but not that of whatever may be needed to explain things. The second variant of simplicism is summarized in the principle of economy of thought, proposed by Avenarius and Mach. According to this principle our aim as cognitive subjects should be to account for our own experience with the least possible intellectual effort. The upholders of this principle used it rather successfully, at the turn of the century, to ignore field physics, attack the nascent atomistics, and try to reconstruct mechanics as a kinematical theory, i.e. dispensing with the concepts of mass and force. We have learned since that simplicity is the seal of ignorance not of wisdom, and simplicism a paralyzing credo: reality is complex and accordingly our representation of it is bound to be complex. (See Planck (1910) and Bunge (1963) for criticisms of simplicism.) Still, the myth of simplicity survives among some philosophers who, even to this day, repeat Mach's dogma that a scientific theory "must provide an economical statement of the regularities which hold between observable phenomena".

3. CHANCE AND CAUSE

3.1. *Probabilistic Hypotheses*

The great majority of hypotheses state associations between putatively objective properties of concrete things, such as atoms, fields, cells, persons, or social systems. There are several kinds of association and correspondingly of association hypotheses. We shall mention the following:

(1) *Qualitative association*, such as "All *A*'s are *B*'s", "Every *A* is accompanied (or preceded or followed) by some *B*", and "The occurrence of *A* prevents that of *B*".

(2) *Statistical association*, such as "*f* percent of *A*'s are *B*'s", "There is a strong positive correlation between schooling and earning", and "There is a strong negative correlation between social participation and crime".

(3) *Functional relation*, as in "Thing *a* reaches (or reached or will reach) place *b* at time *c*", and "The total consumption in any given year is a linear function of the national income in the preceding year".

(4) *Probabilistic association*, as in "The probability that *a* be at place *b* at time *c* equals *p*", and "The probability of an *A* turning into a *B* within the next time period is *p*".

(5) *Descent relation*, such as "All molecules self-assemble from their components", and "Species *A* and *B* have a common ancestor *C*".

(6) *Causal relation*, such as "Gravitation produces acceleration", and "Discontent causes rebellion".

Whereas the hypotheses of the first three types tell us (conjecturally) what goes with what, those of the last two types tell us what comes from what. The probabilistic hypotheses (4), which are a particular kind of functional relations, may represent either regular associations or transformations. The phenomenological (kinematical, black box) hypotheses are all of the types (1), (2), (3), or (4), whereas the mechanismic (dynamical) hypotheses are of the types (4), (5), or (6).

In the research process the various kinds of hypothesis remain distinct but not separate. Thus some correlations suggest or confirm descent or causal hypotheses, and the latter may result from suitably interpreting certain functional hypotheses. This statement calls for some elaboration. Take a random sample from a population, and measure two properties possessed by their members. If the two properties happen to be strongly correlated, it is legitimate (though perhaps false) to conjecture that a suitable partition of the original sample may yield a set of subsamples in each of which the correlation coefficient is maximal, i.e. equal to 1. See Figure 8.4. In other words, a correlation may hide a whole family of functional relations, and be thus just a sign of heterogeneity in the population. (Caution: the converse is not true, i.e. two variables may be functionally related without being linearly correlated. Feller (1968, I, p. 236) offers the following example. Let U and V be variables with the same distribution, hence the same mean, and let $X = U + V$ and $Y = U - V$. Then $\overline{XY} = 0$ and $\bar{Y} = 0$, whence $\rho(X, Y) = 0$. This shows that correlations do not yield general measures of dependence and that they do not generalize functions.)

In the philosophical literature (e.g. Nagel, 1961; Hempel, 1965) statistical generalizations, such as "f percent of A's are B's", and "A and B are strongly correlated", are usually mistaken for probabilistic hypotheses. One reason for this confusion is the empiricist thesis that a probability value is nothing but a long run frequency. This thesis was shown long ago to be

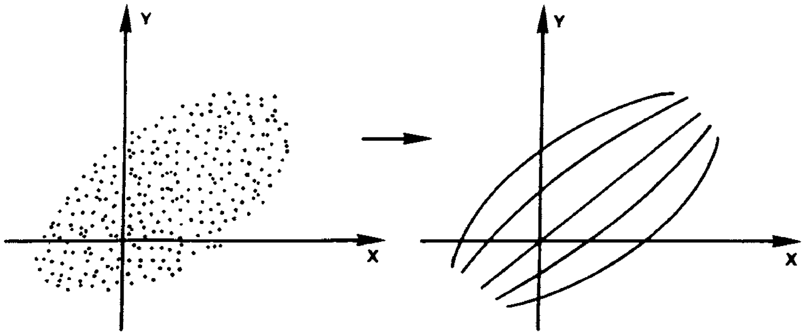

Fig. 8.4. From correlation to functional relation(s).

mathematically false (Ville, 1939). It is also philosophically untenable. For one thing, probability is a theoretical concept whereas frequency is an empirical one. For another, whereas probabilities concern potential states or events, frequencies are of actual states or events. What is true is that some (by no means all) probability statements are tested by confrontation with frequency statements. (See Bunge, 1973a, 1981c.)

Probabilistic hypotheses are theoretical and they involve, either fundamentally or derivatively, probability distributions. A good example of such hypothesis is the Maxwell–Boltzmann distribution of the velocities of the molecules in a gas: Figure 8.5. The operationalist reading of this curve is in terms of the *frequency* with which a molecule will be *found* to have a given velocity. The realist interpretation involves the concept of probability, not frequency, and says nothing about our finding anything: it says that the probability or propensity that a molecule will have a certain velocity is such and such—whether or not the velocity is measured. Considerations of measurement appear only at the test stage, when probability distributions are contrasted with frequency distributions or histograms, such as that of Figure 8.6.

A theoretical probability distribution is a very potent hypothesis, for—when conjoined with the suitable definitions—it yields any number of parameters, such as averages, moments and standard deviations (or scatters). In most applications these parameters are global or collective properties of the population concerned, be it a physical, biological, or social system. Thus the mean velocity of a gas and the average age of an animal population are global (or nondistributive) properties of the whole. However, in the quantum theory every individual entity is assigned a whole

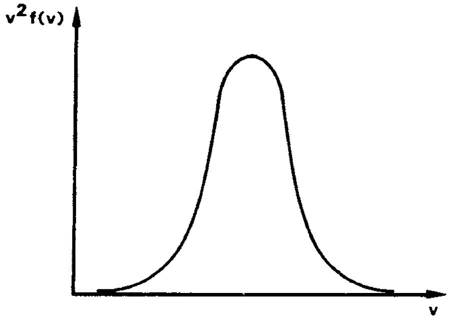

Fig. 8.5. The Maxwell–Boltzmann distribution for the probability that a molecule in a gas in equilibrium has a given velocity.

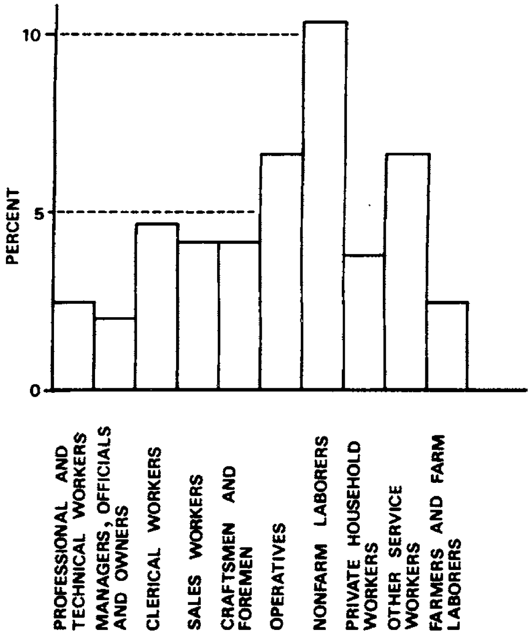

Fig. 8.6. Unemployment rates by occupation in the U.S.A. during the 70's.

set of probability distributions (of position, linear momentum, etc.). In either case some of the parameters calculated from a distribution can be checked by comparison with the data contained in a frequency distribution (histogram).

Whether classical or quantum-theoretical, probabilities are objective (though perhaps falsely posited), not subjective. (Objective probabilities are often called 'propensities', and subjective probabilities 'credences', 'degrees of rational belief', or 'personal probabilities'.) That this is so can be seen from the following considerations. First, all the probabilities occurring in science and technology concern concrete things rather than our beliefs about them. Second, in probability matters our beliefs are expressed by our favoring certain probability distributions over others—hence they are formulated as metastatements such as "I favor such and such distribution". Third, we are supposed to check such hypotheses by contrasting our probabilistic hypotheses, and their consequences, with empirical data. (For details see Bunge, 1981c.)

A probability distribution may be proposed to explain an empirical frequency distribution or it may suggest collecting some statistic. Everyone should feel free to propose probability distributions, whether on the strength of data, or of theoretical considerations, or by sheer guessing. The only conditions are that (*a*) the hypothesis be checked, and rejected if found false, and (*b*) the thing or process in question be, or be assumed to be, random in some respect. The first condition is obvious to anyone save an extreme subjectivist. The second condition is ignored by most of the philosophers interested in probability, as shown by the popularity of the procedure of assigning probabilities to propositions such as hypotheses and data. However, no randomness, no chance for probability.

If proposed prior to the collecting of empirical data, a probability distribution is said to be *prior*. Thus Maxwell and Boltzmann proposed the Maxwell–Bolztmann distribution several decades before it was possible to check it experimentally—and even before the hypothesis of the existence of atoms and molecules was generally accepted. A prior distribution is not something to be accepted or rejected on subjective grounds, but a hypothesis to be put to the test. Guessing prior probability distributions is methodologically akin to guessing any other functional hypotheses; and guessing probability values is no different from guessing distances or ages. All such judgments, whether of probabilities or of sizes, are guided by incomplete data and by hunches (sometimes called 'heuristic rules') and are, of course, subject to error (Tversky and Kahnneman, 1974). There is nothing wrong with such errors in subjective estimates of probabilities, or of anything else, as long as we have the chance of revising them—which is usually the case in science and technology but not so in everyday affairs, where bad mistakes of the sort are often paid dearly.

What is definitely wrong is the subjectivistic (or personalist) doctrine of probability (de Finetti, 1972; Savage, 1972). According to this doctrine probabilities (*a*) express nothing but credences, and consequently (*b*) they are always estimated subjectively. If a scientist or a technologist were to proceed in this way he would be charged with violating the ideal of objectivity. The theoretical physicist, chemist, or geneticist who calculates the probability of the transition of a system from one state to another does so not on a valid hunch but on the basis of law statements such as the Schrödinger equation. And he takes it for granted that, if the scientific theory is correct, the calculated probability quantitates the tendency or propensity of the system to make such a transition.

The science of chance was born only a few centuries ago, and it is not yet taught in elementary school. Consequently we are still unfamiliar with the ideas of randomness, correlation, and their kin. This gives rise to the gambler's fallacy, which may lead an individual to his ruin. There is an even more basic mistake, which is betting in games of chance. Consider the so called "lottery paradox" (Kyburg, 1961), which has elicited the flow of so much philosophical ink. A person ignorant of the nature of chance bets that the (presumably fair) die he is rolling will not come up face *n*, where *n* ranges between 1 and 6. If each of these six statements is taken as true, their conjunction must be accepted as well—but of course it is false, because the 6 possible events are mutually exclusive. The paradox is dissolved on realizing that each of the above statements of the form "The die will not come up *n* when tossed" is groundless. A probabilistic analysis of the game of dice allows one to make only probabilistic statements, such as "In the long run this die will not come up *n* about five out of six tosses". The moral is obvious: Don't bet if you can avoid it.

Another example is the classical finding that most lay subjects are biased towards conjecturing associations (i.e. joint occurrences of properties or events) and neglect negative instances (Smedslund, 1963). Experienced nurses were presented with a 2 × 2 contingency (or presence–absence) table such as this one:

		Disease	
		Present	**Absent**
Symptom	**Present**	*a* 37	*b* 33
	Absent	*c* 17	*d* 13

85% of the nurses estimated that the symptom–disease correlation was strong, for they focused on the quadrant *a* with total neglect of the other three cells. The actual correlation coefficient is negligible, namely $37/70 - 17/30 = 0.038$. Ward and Jenkins (1965) found similar results working with college students presented with contingency tables concerning the association of cloud seeding with rainfall.

3.2. *Causal Hypotheses*

Whereas the statistician is happy if he finds a strong association between two variables, the scientist is unhappy if he cannot explain it, and the technologist if—for want of knowledge or of means—he cannot alter it. For example, sociologists would like to know why schooling and earnings used to be strongly correlated. Was it that increase in schooling produces a higher earning potential or, conversely, that a higher income makes longer schooling years possible?

Statistical correlations can be explained by hypothesizing (*a*) some underlying probability distribution(s), or (*b*) a third factor influencing, or even generating, the observed associated traits, or (*c*) a causal relation between the two variables—or rather their variations. Let us deal with the latter, which are the most popular and at the same time the most reviled by the empiricist tradition, which regards the notions of cause and effect as remnants of metaphysics. (See Bunge (1959) for details on causation and its philosophy.)

The traditional causal hypotheses are of the form *A is necessary for B*. (Sufficiency may require further concurrent causes.) Since the birth of probabilistic theories in science and technology we must reckon also with semicausal probabilistic hypotheses of the basic form *The probability of A causing B equals p*. In these formulas '*A*' and '*B*' stand for events or kinds of events. Things and their properties do not qualify as causes and effects: only changes in properties of concrete things do. (Hence an initial state cannot be said to cause a final state—the more so since the process in question may be uncaused, i.e. spontaneous.) There would be no causation in an unchanging world, for causation is a mode of becoming, not of being.

In general, a functional relation cannot be read as a causal hypothesis without further ado. For example, although the weight of a body is a function of its volume and specific gravity, these cannot be said to cause the former: weight is an effect of the acceleration caused on bodies by a gravitational field. Some functional relations can be interpreted causally, others cannot. Take for instance a functional relation of the form "$y=f(x)$", where x and y are real variables. If x and y happen to represent events, i.e. changes of some kind, then perhaps x can be interpreted as the cause of y or conversely. If not, we may try the derived formula "$\mathrm{d}y=f'(x)\,\mathrm{d}x$", where $\mathrm{d}y$ is the variation in y corresponding to the change $\mathrm{d}x$ in x. A priori it may be that $\mathrm{d}x$ is the cause of $\mathrm{d}y$, or conversely, or that neither causes the other—i.e. that $\mathrm{d}x$ and $\mathrm{d}y$ are merely conjoined or associated. Which of the three interpretations is the correct one must be found out by additional research, either by looking for underlying mechanisms or by experimentally controlling or inhibiting changes in either variable and measuring values of the other.

Take the well-worn case of the ideal gas at constant temperature in a container equipped with a movable piston, and "obeying" the law

"$pV = \text{const.}$". If the piston compresses the gas, the decrease $-\mathrm{d}V$ in volume is the cause of the increase $\mathrm{d}p$ in internal pressure. But if the gas is allowed to push the piston, the decrease $-\mathrm{d}p$ in internal pressure will cause the increase $\mathrm{d}V$ in volume. Both causal relations are covered by the single formula "$\mathrm{d}p.V + p.\mathrm{d}V = 0$" derived from the gas law. In short, functional relations do not become causal hypotheses unless supplemented by causal interpretations. Moreover in some cases such interpretations cannot be appended. For example, Schrödinger's equation in time does not describe the causal evolution of the state function, because the latter is a probability amplitude. And even in elementary mechanics there are problems that have any desired number of solutions (Truesdell, 1974), so that classical mechanics can hardly be said to be a paragon of causal theory.

Moreover certain nonprobabilistic ("deterministic") models involving nonlinear differential equations have nonperiodic solutions that look random (and are miscalled 'chaotic'). That is, the solutions look totally irregular even to the trained statistician, although they do not contain the probability concept and, moreover, they derive from equations representing nonstochastic processes. See Figure 8.7. This is particularly the case with equations with time delays, capable of representing after-effects such as gene expression or the effect of a temporary hump in the birth curve on the market two decades later. This mock randomness is the more puzzling as only equations with time delays can adequately represent causal relations, all of which are supposed to satisfy the principle of antecedence, according to which the effect emerges after the cause. The investigation of

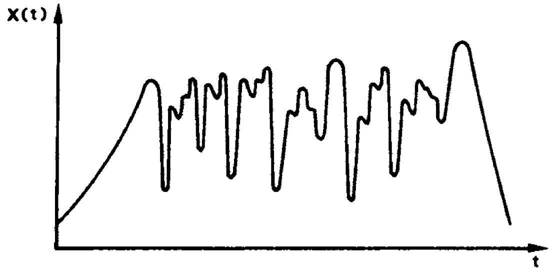

Fig. 8.7. The "deterministic" equation with time delay

$$\frac{\mathrm{d}x}{\mathrm{d}t} = \frac{ax(t-\tau)}{b^n + x^n(t-\tau)} - cx$$

has nonperiodic or "chaotic" solutions for large values of τ and n. See Mackey and Glass (1977). For further examples see R. H. G. Hellman (Ed.) (1980).

this problem has only begun (see, e.g. Hellman, 1980) and it is still to be exploited philosophically.

The above example shows vividly that mere empirical data cannot suggest unequivocally whether causation or mere functional relation, genuine or spurious correlation, or even chance, is at stake. A simpler example is this. Suppose you are given the sequences 0000000000 and 0100111011. You may be tempted to bet that, whereas the first was generated by some causal mechanism, the second was produced by a randomizer. Yet both sequences have the same probability, namely 2^{-10}. In sum, data are not enough to tell the difference between randomness and causation. Nor does intuition, even when accompanied by experience, suffice. We also need some hypothesis about the underlying mechanism—a testable conjecture of course—the more so since certain nonprobabilistic mechanisms give rise to behavior that looks random.

Whereas statisticians are usually content to find correlations, scientists and technologists are interested in discovering whether there is a functional relation, perhaps even a causal one, behind a regression line. This is a tricky problem that a mere contemplation of correlations cannot solve. In fact, although weak correlation disproves conclusively functional relation and causality, strong correlation may suggest either without proving them. Thus the strong correlation between per capita GNP and automobile production can be explained, *prima facie*, in either of the following alternative ways: (*a*) rising GNP causes rises in automobile sales—but then why does it not cause a similar increase in the sales of philosophy books?; (*b*) GNP and automobile sales are two different indicators of industrialization—but then why are they not similarly associated in the industrialized socialist countries?; (*c*) the growth of cities and the inadequacy of mass transportation systems cause the need for more automobiles, a need that can be satisfied by a rising per capita GNP—but then why do the Western European nations exhibit a similar correlation while having generally adequate collective transportation systems? In sum, although strong correlation may suggest causation it does not indicate its direction and, of course, it does not prove it. Monetarist economists have still to learn this lesson, for they like to buttress their hypothesis of the causal efficacy of money with some favorable correlations while disregarding the unfavorable ones. (See Modigliani (1977) for the negative correlation between monetarist policies and prosperity in the post-war U.S.A.)

But why bother with causality if quantum theory, the most fundamental physical theory, is probabilistic? Does this not prove that causality is a myth? This was indeed the impression initially given by the quantum-theoretical revolution, particularly when allied with the positivistic criticism of causality. But on closer examination quantum physics is seen to have causal as well as probabilistic ingredients. Indeed probabilities evolve under the influence of forces—and forces are causes. (More precisely, the form of the probability amplitude depends critically upon the form of the hamiltonian, which represents the forces among the components of the system as well as the forces exerted by the environment on the system.) For example, when a physicist calculates or measures the probability that an atom will scatter an incoming electron within a given solid angle, he determines the propensity of a given event (the two entities coming close together) *causing* another event (the scattering). In short causality has blended with probability.

What holds for physics holds a fortiori for all the other factual sciences. In all of them we find causal hypotheses, sometimes including a chance ingredient, as in the schema "The probability of A causing B is p". Causality, far from having disappeared, is alive and well though now as a component of a richer determinism (Bunge, 1959a, 1982a).

4. REQUIREMENTS

4.1. *Strength and Precision*

We make conjectures all the time but, unless we are fools, we do not assign them all the same status. Upon examination some hypotheses prove to be weaker, or wilder, or less deep, or less testable, or less true, or less useful than others. We should accept only those that pass certain tests—and even so we may have to demote or even discard some of them as new knowledge becomes available. Now, there are several kinds of hypothesis and therefore, presumably, different sets of requirements. Therefore we should start by distinguishing hypotheses with regard to their methodological status.

Our very first distinction is between substantive and nonsubstantive hypotheses. A *substantive* hypothesis is a hypothesis that describes, explains, or forecasts facts of some kind. The phenomenological and mechanismic hypotheses, as well as the probabilistic and causal ones, are substantive. On the other hand the *nonsubstantive* hypotheses are valuational or prescriptive: they guide research and action. We distinguish two kinds of them: methodological and axiological. A *methodological* (or *instrumental*) hypothesis is a tentative statement concerning the methodological status of a statement, a procedure, or a plan—e.g. that a certain formula is, or is not, a suitable axiom or a convenient definition, or that a certain procedure is, or is not, adequate for attaining some goal, or that a certain political tactic is likely to bring victory. And an *axiological* (or *valuational*) hypothesis is a value judgment—e.g. that a given theory is all round better than another, or that a certain action or a given life style is good. Obviously, we make hypotheses of all these kinds in all walks of life, from pure mathematics to mass murder.

We should impose two requirements on hypotheses of all kinds, whether substantive or nonsubstantive. Of two rival hypotheses we should prefer the better grounded or justified, and the one belonging to the wider conceptual system. (This is a norm, not a hypothesis.) The former condition because rationality entails, among other things, the rejection of authority, even that enjoyed by success. The second condition because the wider the conceptual system the more propositions can check the given hypothesis. More on these conditions later on.

Aside from those two conditions, we treat differently hypotheses of different kinds. We prefer the strongest, more precise, deepest, more systematic, and better confirmed substantive hypotheses. These criteria are epistemic, not utilitarian. On the other hand what we expect from nonsubstantive hypotheses is effective guidance. Thus from methodological hypotheses we expect that they help us solve methodological problems of some kind, such as the organization or test of a body of propositions, the gathering of data, the design of artifacts, the outlining of plans, or what have you. And from axiological hypotheses we expect that they help us choose or do the best or avoid the worst. In the remainder of this section we shall deal only with substantive hypotheses, and shall do so in several respects.

From a logical point of view hypotheses may be ordered in respect of strength. A formula A is said to be *logically stronger* than a formula B if, and only if, A entails B. (In turn A entails B, or $A \vdash B$, only when the conditional "If A then B" is logically true, or holds for all interpretations of A and B.) Thus p is logically stronger than "p or q", where q is an arbitrary proposition, i.e. one not necessarily related to p; "p & q" is stronger than either p or q; and an "all" statement is stronger than the corresponding singular statement, which in turn is stronger than the corresponding "some" statement.

Paradoxically, the strongest of all formulas are the logically false ones, i.e. the contradictions, for they entail anything. On the other hand the tautologies, or logically true formulas, are the weakest of all, for they entail nothing but further tautologies, and they follow from no premises. Logic, in short, is self-validating and self-contained—in fact it is the only such epistemic field. For this reason it cannot be invalidated by any factual discoveries. However, this does not entail that logic is detached from the rest of human knowledge. Far from it, logic underlies (is presupposed by) all rational discourse. In particular, every consistent theory contains logic as a proper part. More on logic in Vol. 6.

Whereas in logic we seek to establish the weakest formulas, in all other fields of research we steer a middle course between tautology and contradiction. However, with regard to logical strength there is a marked difference between the course taken in the theoretical branches of a science and that taken in its empirical (laboratory or field) ones. (Except for the formal sciences, all the others have both theoretical and empirical branches. Thus physics is composed of theoretical and experimental physics, and biology of mathematical biology and experimental biology.)

Indeed, in theoretical science we should prefer the *strongest* noncontradictory hypotheses compatible with certain general principles as well as with the relevant examples (in the case of mathematics) or empirical data (in the case of factual science). On the other hand, laboratory and field research should seek to establish the *weakest* nontautological formulas compatible with the most general principles of science, such as the principle of conservation of energy. Such are the data contained in laboratory protocols and in the notebooks of field researchers. They are in principle corrigible in the light of further data or of well-confirmed hypotheses but they do not replace or entail hypotheses.

Let us consider *precision* next. Like concepts, hypotheses come in various degrees of precision, from the ones couched in ordinary language to those couched in a mathematical language. Thus compare "There must be some thing, somewhere, that is doing something to this thing", with "Set A is included in set B". Of all the ordinary language expressions, counterfactuals break the record of imprecision. Thus the sentence 'If A were the case then B would happen' can be interpreted in a number of ways, such as "If A then B, but A is false", and as an injunction to bring about A so as to attain B. This is why counterfactuals do not occur in scientific theories and why it is wrong-headed to try and build exact theories about them.

The most precise formulas are of course those containing exact concepts. But even among mathematical formulas we can distinguish different degrees of precision. Thus an equation is more precise than the corresponding inequality, and a quantitative formula more precise than the corresponding qualitative ones. Compare "f decreases monotonically" with "For all real $t \neq 0, f(t) = 1/t$". There are infinitely many functions that fit the former description, only one that fits the latter. Consequently the chances of being right are greater when proposing an imprecise hypothesis than when proposing a precise one. But scientists are not particularly interested in cheap truths, just as moralists are not interested in passing through wide doors. Other things being equal they prefer the more precise hypotheses because they "say" more.

The preference for precision over imprecision is justifiable only if there is an option. When there is no option we must settle for imprecision—for the time being. This is unavoidable, nay desirable, at the beginning of a research project, when we formulate *working* (or *programmatic* or *schematic*) hypotheses that guide the investigation. Thus the hypothesis that every mental phenomenon is (identical with) the specific activity of some plastic neural system, summarizes an entire research program in physiological psychology—a very fertile one indeed.

Three kinds of working or programmatic hypotheses are of particular interest: functional schemata, existential conjectures, and negative ones. A *functional schema*, such as "Y is some function of X", cries for precision and suggests the search for the exact functional relation between X and Y. It is thus part of a research project aiming at substituting a precise function (e.g. the exponential one) for the indeterminate function symbol F in "$Y = F(X)$". Or take the *existential* hypothesis "There is one genotype for every phenotype". This (partially true) working hypothesis inspires the whole of genetics: in fact, a central task of geneticists is to map gene complexes into phenotypes—a task that is unlikely to be ever completed, so many are the biospecies and their traits. Finally, consider the *negative* hypotheses that there are no microphysical inertial systems, and that the speed of light *in vacuo* fluctuates around c instead of being constant. These suspicions could generate a research line resulting in a generalization of relativistic physics. (Being negative hypotheses they can belong to no theory although they may suggest building a theory complying with them.) In sum, we cherish working hypotheses as parts of research projects. The advancement of knowledge consists, among other things, in a march from programmatic hypotheses to precise substantive ones and, in general, a progression from imprecision to precision.

4.2. *Systemicity and Scrutability*

A third property of hypotheses we must consider is their systemic status, i.e. whether or not they belong to an organized body of knowledge, such as a classification or a theory. Most of the hypotheses we formulate in daily life are stray. Thus we may conjecture that a colleague's dark glances at us are due to jealousy, although we have no theory of jealousy and no reliable jealousy indicators or objectifiers. In advanced science and technology we prefer *systemic* hypotheses, i.e. conjectures belonging to conceptual systems, and distrust the nonsystemic or *stray* ones. The advantages of systemic over stray hypotheses are obvious: (*a*) the hypotheses in a system can join to generate (logically) further hypotheses, and (*b*) systemic hypotheses are supported not only by whatever empirical data may be compatible with them, but also by the other components of the system. See Figure 8.8.

Stray hypotheses may concern (refer to) a large or a small domain of facts. The stray hypotheses that account only for a small subset of the total set of facts it addresses are called *ad hoc* (for that). Here are three examples of stray hypotheses that are also *ad hoc.* (*a*) "Criminals are the product of society". (The same society "produces" a majority of noncriminals.) (*b*) "Underground and cave dwellers have lost their sight for lack of use of their eyes". (Not all such animals are blind. Besides, genes are presumably not affected by luminosity.) (*c*) "The dinosaurs became extinct because their brains were too small to cope with a complex environment". (The dinosaurs had been remarkably successful, i.e. prolific, before the end of the Cretaceous period—at which time many other species became extinct as well.)

Whereas some *ad hoc* hypotheses are proposed to "save the appearances", i.e. to cover or even explain some group of facts, others are

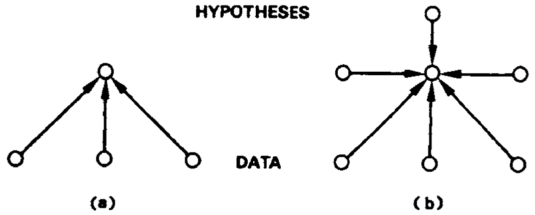

Fig. 8.8. The systemicity of hypotheses. A stray hypothesis (*a*) is supported at best by the data favorable to it. A systemic hypothesis (*b*) is supported also by the other hypotheses in the same conceptual system. The arrows indicate support, not inference.

introduced to save further hypotheses endangered by unfavorable evidence. We call the latter *protective* hypotheses. They are not all alike: whereas some may turn out to be true, others are not even scrutable. We call *bona fide* protective hypotheses those scrutable conjectures that are designed to save other hypotheses, and *mala fide* those which, being introduced for the same reason, are inscrutable. Whereas the former can in principle be shown to be true or false to some extent, the latter cannot.

The hypothesis that the naturally occurring elements are mixtures of different isotopes was initially framed to save the atomic hypothesis: it was testable and eventually found true. Likewise the hypothesis that an organism does not respond in the same way every time it is subjected to a given stimulus, for it keeps changing its internal state, was originally introduced to save stimulus–response psychology but it turned out to be true. Both are examples of *bona fide ad hoc* protective hypotheses. On the other hand the psychic's claims that his failures are due to somebody's hostility inhibiting his paranormal abilities, and the psychoanalytic fantasy that most people do not exhibit their Oedipus complex because they have repressed it, are paragons of *mala fide* protective hypotheses.

Mala fide protective hypotheses are peculiar to everyday reasoning and pseudo-science. On the other hand *bona fide* protective hypotheses are very common in science, technology, and the humanities. Sometimes they are introduced to discard data that collide with well established theories. (Imagine an engineer rejecting classical mechanics because his bridge collapsed.) At other times *bona fide* protective hypotheses are framed to shield new theories from rash criticism. (Imagine Darwin giving up his theory of evolution because of the gaps in the fossil record.) There is nothing wrong with a protective hypothesis as long as it is *bona fide*, i.e. independently testable. (For further examples see Bunge, 1967a, Ch. 5, Section 5.8, and 1973b, Ch. 2, Section 1.) We shall come back to this question in Ch. 11, Section 2.1.

The fourth and last property of hypotheses we need to look into in this chapter is scrutability; truth and utility will be examined later on. A substantive factual hypothesis can be said to be *scrutable* or *testable* if, and only if, (*a*) it refers exclusively (whether truly or falsely) to real (material) entities, and (*b*) it can be checked for truth by contrasting it with data or with the bulk of accepted knowledge. Otherwise the hypothesis is inscrutable or untestable. A hypothesis that is both inscrutable and stray (nonsystemic) may be called *wild*. Typically, pseudo-scientific speculation is wild.

Scrutability, a methodological predicate, does not coincide with intelligibility, a psychological one. A bold new hypothesis may be both scrutable and hardly intelligible to but a few initiates. Nearly every profound innovation is baffling: "When the great innovation appears, it will almost certainly be in a muddled, incomplete and confusing form. To the discoverer himself it will be only half-understood; to everybody else it will be a mystery. For any speculation which does not at first glance look crazy, there is no hope" (Dyson, 1958, p. 80). There is no great and interesting research, in any field, without speculation; the only condition we must impose on it is that it be scrutable, not wild.

Some sciences are and will probably remain largely speculative. Cosmology, palaeontology and history are among them. Take for instance the speculations of palaeontologists. Far from being wild they are guided by (*a*) fossils, (*b*) associated remains (e.g. those of plants and prey), (*c*) considerations of homology with living organisms, (*d*) geological data and hypotheses, and (*e*) general biological and even purely mechanical principles concerning, e.g., posture and locomotion. For example, it is now possible to argue for the hypothesis that all of the great dinosaurs were water dwellers, as well as for and against the fantastic (but not wild) conjecture that dinosaurs, unlike their modern successors, were warm-blooded and therefore had a quick metabolism. Thus it is now possible to cast "a cold look at warm-blooded dinosaurs"—the title of a recent scientific symposium (Thomas and Olson, 1980).

To conclude. When considering hypotheses for test or adoption we should generally prefer depth to superficiality, logical strength to weakness, precision to inexactness, systemicity to isolation, and scrutability to untestability. However, imprecise conjectures are acceptable if they are promising research guides, i.e. programmatic hypotheses. And superficial and relatively weak hypotheses may be unavoidable if we need quick practical results. What we cannot accept under any circumstance, in any walk of life, are inscrutable hypotheses, particularly of the protective kind, for they are the mark of dogmatism.

5. Concluding remarks

Dogmatic rationalists, intuitionists and radical empiricists have no use for hypotheses: the former own indubitable a priori axioms, the intuitionists are endowed with a special direct insight (some of them even with what Husserl called *Wesensschau*, i.e. vision of essences), and the radical empiricists, more modest, are content with perceptions and images. Even the great Russell, during his logical atomism period, proposed to eliminate what he called 'inferred entities' (i.e. hypothesized objects) in favor of constructions out of certified, in particular perceptible, entities. He proposed the rule "Whenever possible substitute constructions out of known entities for inferences to unknown entities" (Russell, 1914). And he applied this maxim to the analysis of matter, which he dissolved into phenomena. In a similar vein, operationists and members of the Vienna Circle attempted to characterize electrons and other transempirical entities, not in terms of their objective properties—the way the theories of matter do—but in terms of pointer readings or some other empirical operations. Fortunately scientists did not follow up this anthropocentric program—except of course during their occasional forays into philosophy. They went on framing and checking increasingly sophisticated hypotheses about hypothesized (but supposedly real) entities such as fields and subatomic particles, extinct organisms and societies, the interior of stars and of brains, and so on. Humanists and technologists behave similarly: far from avoiding conjectures they frame them all the time; they try to avoid only wild hypotheses.

Hypothesizing is just as necessary as gathering data, because to investigate is to handle problems, and to solve a problem is to frame a hypothesis, or find a set of data, that may satisfy the condition (generator) of the problem. Hypotheses fulfill a number of functions in ordinary life, science, technology, and the humanities. Some of them summarize experience and others generalize it. Some allow us to deal with real or presumptively real but imperceptible facts, still others trigger reasonings or fill gaps in them. Finally, others guide (or block) entire research plans, in particular the design of observations. The services hypotheses render are so many and important that any attempt to dispense with them would be as silly and ineffectual as trying to do without any data.

That the ultimate components of the universe are fields and particles, and all of these are restless; that the sun and the planets are roughly spherical and compose a system; that cells are the units of life and all modern organisms descend from others that lived long ago; that every society is composed of an economy, a polity and a culture—however primitive—and that these subsystems interact with one another vigorously—all these are hypotheses, not data. In fact most of our scientific knowledge is hypothetical, though of course not all conjectures are equally tentative: some of them—such as the ones we have just listed—are as well established as the firmest of data. They are supported not only by data but also by further hypotheses belonging to some conceptual system or other. Conceptual systems is what we shall study next.

CHAPTER 9

SYSTEMATIZING

All humans crave for knowledge, and not just any old heap of bits of information but systems, i.e. sets of epistemic items possessing unity and coherence. The easiest way to obtain both unity and coherence is through radical simplification and reduction to a few basic ideas. This is the way nonscientific ideologies are fashioned.

Simplification is unavoidable and reduction is desirable—up to a certain point, beyond which they involve inadmissible distortions. Reality is much too varied and changeable, creativity much too incessant, and rationality much too demanding, to tolerate simplistic systems. We need conceptual systems capable of accounting for diversity and at the same time possessing the desirable properties of unity and consistency. These systems are classifications and theories.

Despite the craving for conceptual systemicity, there is still some distrust for classification and theorization. We often say we do not like being pigeonholed, and that a gram of practice is worth a ton of theory. This distrust has several sources: sheer anti-intellectualism, misunderstanding of the nature of classification and theory, and ignorance of their role in civilized life. In this chapter we shall study classification and theory, without which man would lead a rather brutish existence, for they help us understand the world and transform it.

We distinguish different degrees of epistemic systemicity or cohesion: the mere collection of bits of information, the context, the classification, the doctrine, the theory, and the system of theories. A catalogue, such as a telephone directory, is an instance of an unstructured set of epistemic items. A context is a more or less loosely knit collection of propositions referring to a single domain. Stories, flow diagrams, wiring diagrams and organigrams are instances of contexts. A context need have no logical structure, so that knowledge of one item of it does not allow one to infer anything about other members. But, by virtue of its definite reference, a context has referential or ontological unity. In Vol. 1, Ch. 2, Section 3.4, we characterized a conceptual context as an ordered triple $\langle P, Q, R \rangle$, where P is a set of propositions, Q the set of all predicates occurring in P, and R the set of referents of the predicates in Q.

Classifications, doctrines, theories (in particular models) and systems of theories are contexts possessing logical as well as referential unity. A classification is a system of propositions concerning items of some kind (e.g. organisms) and their inclusion relations (e.g. "Species S is included in genus G"). A doctrine is a context such that some of its propositions are logically related to others: it need not constitute a hypothetico-deductive system and it need not even be consistent. A theory is a hypothetico-deductive system, i.e. a system of propositions every one of which is either a premise or a logical consequence of a group of premises. And a system of theories is a collection of mutually consistent theories and of bridges among them.

1. CLASSIFICATION AND THEORY

1.1. *Classification*

It seems that all sentient organisms are capable of perceiving certain types and patterns—visual, auditory, tactual, gustatory, olfactory, spatial, temporal, and others. Now, a *type* is whatever is shared by a mass of apparently unrelated items, and a *pattern* is whatever is invariant in a mass of items. Thus all human faces, however great their individual differences, have the same type or general shape; and all waves fit the same general pattern even though they differ in amplitude and frequency. Since we can perceive types and patterns, by the same token we can discard individual differences and thus throw some information away. We do this either from the start or as a result of analysis. In the former case we grasp types and patterns in a synthetic way, sometimes intuitively; in the latter case we conjecture, test, and conjecture again until we grasp type or pattern. In this section we shall study typification, i.e. the formation of types and systems of types.

We saw in Ch. 5, Section 1.2 how classes are formed, namely by grouping together individuals that share certain properties, such as having the same mass or the same descent, even if they differ in all other respects. A single attribute A and its complement not-A allow one to make black or white statements such as "c is an A" and "c is a non-A". A pair of attributes, A and B, allow us to form four different propositions: "c is an A and a B", "c is an A and a non-B", "c is a non-A and a B", and "c is a non-A and a non-B"—i.e. the components of a 2×2 contingency table. In general, for n attributes we may construct 2^n propositions for any given individual. Each such set is called a *Boolean partition*. We use such qualitative partitions every day.

For certain purposes we must use quantitative predicates, such as distances and probabilities, which allow us to form infinitely many propositions, and so infinitely fine partitions. Think, e.g. of the infinitely many distances a moving point can be from a fixed center. We call these *Cartesian partitions*. See Figure 9.1. Because a Cartesian partition contains infinitely many cells, it provides a far richer representation of reality than any Boolean partition—so rich, in fact, that it incorporates information that cannot be obtained by observation and measurement. (Any run of measurements yields only a finite number of numerical values.) It is thus a formidable analytic tool and, by the same token, an inadequate categorization tool, for categorizing is lumping as well as splitting. Let us take a closer look at classification, whose principles are often misunderstood by its most conspicuous users, namely the biologists.

A *classification* of a given collection of individuals—be they concepts, concrete things, events, or what have you—is a conceptual operation with the following characteristics:

(i) each member of the original collection is assigned to some *class*;

(ii) each class is composed by some of the *members* of the original collection, and no class is composed of subclasses;

(iii) each class is a *set* the membership of which is determined by a predicate or a conjunction of predicates;

(iv) each class is *definite*, i.e. there are no borderline cases—which is ensured by employing only definite or exact predicates and avoiding vague ones such as "young" and "distant";

(v) any two classes are either mutually *disjoint* (i.e. have no members in common) or one of them is *included* (contained) in the other: if the former

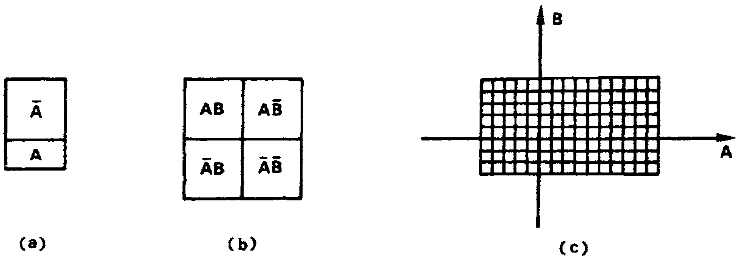

Fig. 9.1. Categorizations. (*a*) Dichotomy. (*b*) A Boolean partition on the basis of two qualitative predicates. (*c*) A Cartesian partition on the basis of two quantitative predicates.

they are said to belong to the same *rank*, otherwise to different ranks;

(vi) only two relations are involved: the *membership* relation ($\in$) holding between the individuals of the original collection and the first rank classes, and the inclusion relation ($\subseteq$) that relates classes of different ranks (e.g. species to genera);

(vii) every class of a rank higher than the first equals the *union* of some or all classes of the immediately preceding rank (e.g. every genus equals the union of its species);

(viii) all the classes of a given rank are *pairwise disjoint* (do not intersect), so that no item in the original collection belongs to more than one class of the same rank;

(ix) every partition of a given rank (e.g. every grouping of the original collection into species) is *exhaustive*, i.e. the union of all the classes in a given rank equals the original collection;

(x) a classification violating any of the above conditions must be repaired or given up.

Clearly dichotomies, such as existent/nonexistent, satisfy all of the above conditions. But they are trivial classifications because they involve a single rank, whereas nontrivial classifications are "vertical" as well as "horizontal". This requires seizing on more than one property. (For example, two attributes, P and Q, elicit the formation of two species, namely $S_1 = \{x|Px\}$ and $S_2 = \{y|Qy\}$, and one genus, namely $G = \{z|Pz \text{ or } Qz\} = S_1 \cup S_2$.) Now, unless the two predicates are mutually incompatible, such as sitting down and running, they may induce the formation of partially overlapping classes. Therefore seizing on arbitrary predicates will not produce a classification proper except by accident.

The only method for producing a classification proper, i.e. a categorization satisfying the nine conditions listed above, is the one based on *equivalence relations* such as those of congruence, homology, common descent, and same age bracket. In fact every such relation splits the set on which it is defined into mutually disjoint (exclusive) and exhaustive (inclusive) sets. These sets are called *equivalence* (or *homogeneous*) classes, and the family of such classes the *partition* of the given set S by the given equivalence relation $\sim$, or $P = S/\sim$. See Figure 9.2a. For example, T shirts for men come in three different sizes, so that the relation "the same size as" ($\sim$) partitions T thus: $\mathrm{T}/\sim\, = \{\mathrm{S},\mathrm{M},\mathrm{L}\}$, where $\mathrm{S} \cap \mathrm{M} = \emptyset$, $\mathrm{S} \cap \mathrm{L} = \emptyset$, $\mathrm{M} \cap \mathrm{L} = \emptyset$ (condition viii above), and $\mathrm{T} = \mathrm{S} \cup \mathrm{M} \cup \mathrm{L}$ (condition ix). In this case the species are S, M and L, and the genus coincides with the original set T. A more sophisticated example is the formation of clades on the basis of homologies such as that between the forelimbs of man, seal, and bat.

Obviously there are as many partitions as equivalence relations. Thus when classing fossil vertebrates one may focus on the conformation of the hip bones, or the possession or lack of a predentary bone in the lower jaw, or the conjectured mode of locomotion, or the conjectured habitat, etc. Each equivalence relation induces its own partition of the given set. Consequently using n different equivalence relations $\sim_1, \sim_2, \ldots \sim_n$, we obtain n partitions $P_i = S/\sim_i$, some of which may be identical. This family of partitions may be pictured as a stack of disks, every one representing the same original pie cut in different ways. See Figure 9.2b.

Once a first partition $P_1 = S/\sim_1$ of the original collection has been effected, we have completed the first rank of the classification: it consists of

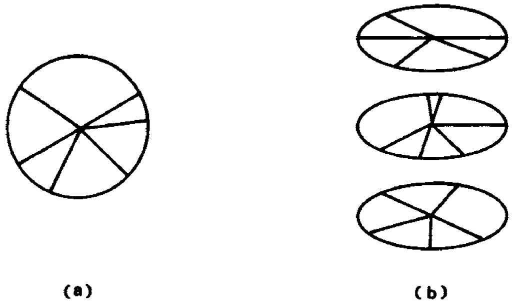

Fig. 9.2. (*a*) Partition of a collection by an equivalence relation. Each sector (subset) is homogeneous in the given respect, and the union of all the sectors equals the original set. (*b*) A family of partitions of a given set.

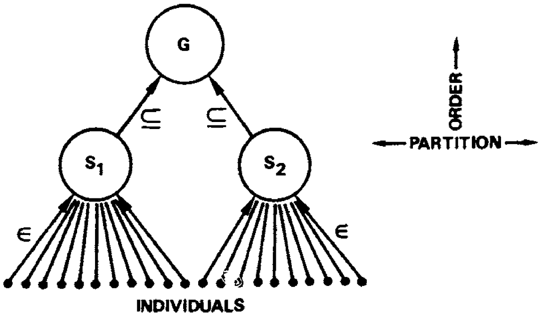

Fig. 9.3. Individuals, species, and genera. Each individual belongs to (∈) some species (lowest order taxon), and each species is included (⊆) in a genus.

species (or subspecies, or varieties). These species may be grouped in turn by using a second equivalence relation $\sim_2$, this one defined on the family P_1, i.e. $P_2 = P_1/\sim_2 = \{G_1, G_2, \ldots G_m\}$. The members of this partition are called *genera*. A third equivalence relation, this one defined on P_2, will induce the formation of the third rank of the classification, namely that composed by *families*—and so on. See Figure 9.3.

To recapitulate, these are the steps in a classification process:

0. A set S of individuals is given or produced.
1. Find a "significant" equivalence relation $\sim_1$ on S.
2. Partition S by $\sim_1$, i.e. form the collection of species $P_1 = S/\sim_1 = \{S_1, S_2, \ldots S_n\}$.
3. Find a "significant" equivalence relation $\sim_2$ on P_1.
4. Partition P_1 by $\sim_2$, i.e. form the family of genera $P_2 = P_1/\sim_2 = \{G_1, G_2, \ldots G_m\}$, such that every member of it be the union of some (one, two or more) species.
5. Repeat the process for the higher ranks as far as necessary or convenient.

One may also invert the process, i.e. start by partitioning the original collection into genera, or even higher rank classes, and proceed to distinguishing subsets within them. For example, the fisherman probably starts by partitioning all fish into edible and inedible—an artificial partition for it is anthropocentric not ichthyocentric. The equivalence relation he uses is "as edible as". He may then proceed to divide the class of edible fish into those which are easy to fish and those which are not. This second equivalence relation, namely "as easy to fish as", is said to *refine* the former. To take a more interesting example, suppose we start with the order primates, and distinguish within it the family of hominids, which in turn includes the genus *Homo*, which in turn includes our own species *Homo sapiens sapiens*. Implicit in this classification are three different equivalence relations that are not always spelled out explicitly. (In fact most biologists partition and order in a rather intuitive way, not caring much for taxonomy, or the methodology of classification. They often pay for this with mistakes or barren controversies. See, e.g. Ghiselin (1981) and the ensuing discussion.) As we descend from the higher to the lower rank classes we do so with the help of finer and finer equivalence relations.

Every classification has two dimensions: the horizontal one attached to the relations of membership ($\in$) and equivalence ($\sim$), and the vertical one linked to the inclusion relation ($\subseteq$). Every good classification is then a trivial example or model of elementary set theory. But not all classifications satisfy every one of the nine conditions we listed a while ago. In particular, some classifications are made with the help of vague or inexact predicates, such as color and shape predicates. And others, actually the great majority, are not exhaustive for want of information. (We keep discovering, inventing or making objects belonging to formerly unknown species.)

Even if a partition is performed with the help of an exact predicate, and therefore an exact equivalence relation, the result may be unsatisfactory because the predicate may be superficial and therefore incapable of bringing about the unity or systematicity we want. For example, the original nomenclature of biocatalyzers (enzymes) was based on the equivalence relation "acting on the same molecule". I.e., if X names the molecule on which enzyme Y acts, then the name of Y is *X-ase*. (Thus arginase catalyzes the hydrolysis of arginine to ornithine and urea.) As the number of known enzymes climbed up to the thousands this nomenclature became impractical. The International Enzyme Commission produced a systematic partition, hence nomenclature, based on a functional description of enzymes. In other words, the new equivalence relation is "having the same function". For example, all the enzymes that catalyze hydrolises are called *hydrolases*, and those that isomerize, *isomerases*.

A clear case of superficiality is that of *artificial* partitions, i.e. those based on traits that, far from being primary and intrinsic, are secondary or concern our relation to the objects concerned (e.g. their external appearance or usefulness). Inevitably, empiricism and pragmatism enjoin us to stick to artificial classifications. And nominalists do not care what classification one may adopt for, according to nominalism, a general sign, such as 'human', does not designate a natural kind but denotes severally the individuals it points to. In other words, according to nominalism the *fundamentum divisionis* of every classification is arbitrary, without a real counterpart: every classification is artificial, and so no classification is better than any other one.

On the other hand, realism recommends natural classifications and, among these, prefers those based on deep or essential properties, in particular laws. (For the notion of a natural kind see Vol. 3, Ch. 3, Section 3.3, and for a defense of nomological essentialism, *ibid.* Ch. 2, Section 4.2.) Essential properties are the basis of essential equivalence relations, which in turn elicit essential or basic partitions—as opposed to accidental or superficial ones. In short, classifications come in several depths, and we should prefer the deepest of all for being the more realistic. (For the notion of depth recall Ch. 8, Section 2.2.) This does not entail that the classes themselves can be more or less real: every class is a concept, but whereas some concepts represent reality others do not. Thus, whereas the set formed by this book and the reader's last dream does not constitute a natural kind, all the bits of copper, and all the hominids and their descendants, do.

Now, mere perception is bound to lead to superficial partitions. Deep partitions call for hypotheses and, in particular, law statements, i.e. formulas about patterns. And, because law statements belong (by definition) to theories, if we want deep classifications we need theories, the deeper the better. Good examples of the power of theory to inspire deep classifications are contemporary biological systematics (based on the theory of evolution), the periodic table of the elements (based on the atomic theory), the classification of hadrons based on the quark model, and the classification of materials based on their constitutive relations or specific laws.

Classing and theorizing are then mutually complementary activities. Categorizing precedes theorizing if only because every theory is about some category of objects. In turn, theory allows one to refine the coarse and shallow pretheoretical classifications. Moreover a classification *is* a theory of a kind. Indeed, unlike the propositions in a catalogue, those in a classification are logically related: they compose a system with logical unity. Thus from the statements that all mammals are vertebrates, and all vertebrates animals, it follows that all mammals are animals. To be sure this piece of knowledge is not a surprising new theorem but was available from the start, but the point is that it is a systemic proposition, not a stray one. Into a classification we pour all we know about certain kinds, and from it we expect no new knowledge. Classifications summarize and order available knowledge, and thus comply with the requisite of empiricism, which prohibits speculation.

Classifications may be dubbed *finite theories*, in contrast to ordinary theories, which contain infinitely many propositions, so that by investigating them we are bound to obtain propositions we did not know before. (See the next section.) For the same reason classifications have a very limited explanatory power. For example, the statement that men and monkeys are primates explains our similitude to our cousins, but only because this similarity was used to construct the order of primates. And what predictive power a classification may have is strictly heuristic, for it stems only from the gaps (e.g. missing links) in it rather than from any explicit statements. For example, the theoretical classification of hadrons based on the quark model predicted the existence of the omega-minus particle, which was eventually found in 1964. A complete classification of known items has no predictive power at all. If we want prediction and explanation we must progress from classification to theory. This we shall do anon.

1.2. *Theory*

From a logical point of view a theory is a logically organized set of statements concerning objects of some kind, i.e. it is a systematic context. At the beginning of this chapter we recalled that a context is defined as an ordered triple of sets: statements-nonlogical predicates occurring in the latter-domain (reference class) of such predicates, or $\mathscr{C} = \langle P, Q, R \rangle$ for short. Since a theory is a logically organized context, it can be characterized as a quadruple $\mathscr{T} = \langle P, Q, R, \vdash \rangle$, where $\vdash$ is the entailment relation that glues the members of P into a system. More precisely, a theory is a *context closed under deduction*, i.e. such that every statement in it is either a premise or a deductive consequence of a set of premises.

If the theory concerns exclusively conceptual objects, such as numbers or philosophical ideas, it is said to be *formal*. If the domain or reference class R of a theory contains factual items, such as molecules or societies, it is said to be *factual*. (Whereas a formal theory contains no reference to factual items, a factual theory may contain not only factual statements but also statements about properties of its own concepts. Thus a theory of change will contain mathematical statements concerning the properties of the functions representing changing properties.) The root difference between a formal and a factual theory lies in the domain R of individuals, or reference class. This difference is semantic and it will occupy us in Section 2.2. In the present section we shall focus on the structure of theories.

That a theory is a logically organized context means that (*a*) a theory is "based on" (presupposes or contains) some theory of logic, usually the predicate calculus with identity, and (*b*) whereas some formulas of the theory are premises, others are logical consequences of some such premises, or even consequences of such consequences—all of them derived with the help of the underlying or presupposed logic. The premises of a theory are either postulates (axioms) or definitions. The consequences of the postulates or definitions are called 'theorems', and the special cases or immediate consequences of axioms, definitions or theorems, are called 'corollaries'. The postulates and their consequences "say" something about the referents of the theory (or members of its domain R), or some

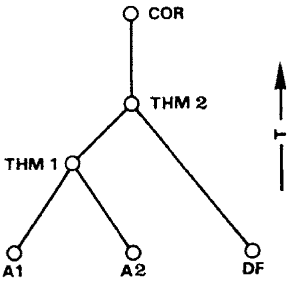

Fig. 9.4. Finite fragment of a theory based on two axioms and one definition. The total theory cannot be pictured because it is a graph with infinitely many nodes (formulas) and edges (logical relations).

concepts of the theory (members of the set Q of predicates), or about relations between concepts and referents. On the other hand a definition links two or more concepts of the theory. See Figure 9.4.

Example 1. Theory of partial order

$A0$ The predicate calculus with identity.
$A1$ R is a nonempty set.
$A2$ For all x in $R, x \leq x$ (reflexivity).
$A3$ For all x and y in $R, x \leq y \,\&\, y \leq x \Rightarrow x = y$ (antisymmetry).
$A4$ For all x, y and z in $R, x \leq y \,\&\, y \leq z \Rightarrow x \leq z$ (transitivity).
Df1 R is *partially ordered* = R satisfies the above axioms.
Df2 R is a *chain* = $\leq$ holds between any two members of R.
Df3 For all x and y in $R, x < y = x \leq y \,\&\, x \neq y$.
Thm1 For all x, y and z in $R, x \leq z \,\&\, z \leq y \,\&\, x = y \Rightarrow x = z$.
Thm2 For all x in $R, \neg(x < x)$.
Cor For all x, y and z in $R, x < y \,\&\, y < z \Rightarrow x < z$.

This is a formal theory, although it can be interpreted in factual terms, e.g. by letting R be the set of bodies and $\leq$ the relation of being less heavy than, or R the family of nations and $\leq$ the relation of being less developed than. It is so simple and general a theory that it underlies (is presupposed by) a host of richer theories, particularly in abstract algebra. By introducing further concepts, such as those of immediate successor, first and last element, greatest lower bound, and least upper bound, richer abstract theories can be built, such as lattice theory and filter theory.

The zeroth axiom $A0$ constitutes the *formal background* of the theory, which in this case is nothing more than ordinary predicate logic with identity. That and the other four axioms and the three definitions compose the *foundations* of the theory. In this case all the axioms concern members of the reference class and their mutual relations. The theory does not contain any semantic axioms (meaning assumptions), i.e. hypotheses about the relation between the specific predicate of the theory, namely $\leq$, and its referents or members of R. In other words, the theory is strictly formal. Its interpretation in factual terms would require the addition of two semantic postulates, one for R, the other for $\leq$—e.g. that R is a set of organisms and $<$ the relation of descent.

Example 2. Theory of exponential growth

*A*0 Ordinary predicate logic with identity plus elementary infinitesimal calculus.
*A*1 R is a nonempty set.
*A*2 F is a real valued function on the cartesian product of R by T, where T is a subset of the real line.
*A*3 F is differentiable with respect to its second argument.
*A*4 The rate F of change of F with respect to its second argument is proportional to F itself, where the proportionality constant is a positive real number depending on the individual (i.e. it is a real valued function on R).
*A*5 'T' represents time.
*A*6 'F' represents the intensity of property P of things of kind R.
Df The relative rate of change of F equals $\dot{F}/F$.
*Thm*1 The relative rate of change of F is constant. (By A4 and *Df*.)
*Thm*2 F grows exponentially. (By *A*4 and certain principles of the infinitesimal calculus.)

The formal background of this theory is far richer than that of the previous theory for, in addition to logic, it presupposes a bulky chapter of mathematics. Thus, because F is assumed to be a continuous function, it has infinitely many values, one for each time and each value of the relative rate of change. That is, *Thm*2 is actually a nondenumerable infinity of formulas of the form "$F(t) = F(0) \exp(kt)$", where $F(0)$ is the initial value of F, k the relative rate of change, and t is in T. Contrast this infinite richness with a singular qualitative hypothesis such as "All ravens are black". (And yet our theory is about the simplest that can be stated with the help of the infinitesimal calculus.) Nor is a hypothesis of continuity necessary to build theories with infinitely many formulas. The underlying logic itself contains infinitely many tautologies. And any theory that presupposes number theory has not only infinitely many formulas but also infinitely many concepts: ... -2, -1, 0, 1, 2, ... Such infinities are usually manageable thanks to the concept of a set and a suitable notation. Thus instead of listing all the integers, which would be impossible anyway, we introduce the single symbol '$\mathbb{Z}$'. Likewise in defining, say, the infinitely many coefficients of a power series one just writes the *n*th coefficient c_n.

Our growth theory is a factual theory, as shown by the postulates *A*5 and *A*6, which are semantic assumptions and, more particularly, hypotheses concerning relations between concepts in the theory and things and processes outside it. (Actually *A*6 is only a semantic axiom schema, for it specifies neither the referents nor the property P.) In other words, when joined to *A*5 and *A*6, *A*4 is a factual hypothesis and moreover a testable one. To be sure, it cannot be tested directly but only through its consequences *Thm*1 and *Thm*2. On the other hand the axioms of the theory of partial order are not testable: they may be regarded as constituting an axiomatic (hence implicit) definition of the relation "$\leq$". What can be checked is only the conjecture that this or that set satisfies those axioms, i.e. is a model of the theory of partial order. In sum, the difference in reference entails a difference in testability.

Note that our theory of growth is kinematical, not dynamical or mechanismic. Indeed it assumes no growth mechanism. On the other hand, a mechanismic theory of growth would contain statements concerning the mode of growth—e.g. by self-assembly prompted by intermolecular forces, or by cell division, or by sexual reproduction. In such a theory the law statement *A*4 would occur as a theorem, not as a postulate—and possibly in a wider form making room for random fluctuations around the central exponential trend. The demotion of axioms to theorems is a good indicator of increasing depth and therefore power. Thus the famous competitive exclusion principle of ecology, namely "Different species occupy different niches" (or "No two species occupy the same niche"), can be derived from the assumption that the members of different species have different enzymes and, as a consequence, different resource needs and different possibilities of exploiting the environment.

We have just made tacit use of the notion of subtheory, or part of a theory that is itself a theory rather than an arbitrary fragment of it. Thus a mechanismic theory of exponential growth includes, as a subtheory, the kinematical theory of growth. (In general T_1 is a *subtheory* of T_2 if, and only if, T_1 is a theory and T_2 entails T_1 or, equivalently, every formula of T_1

is included in T_2.) The subtheory may or may not have a smaller reference class than the theory of which it is a part: what matters is that all the statements of the former belong in the larger theory but not conversely. Thus particle mechanics is a (tiny) subtheory of body (continuum) mechanics, and the theory of the linear oscillator is in turn a subtheory of particle mechanics.

Subtheories should not be mistaken for *specific theories* or *models* of things of a certain kind. A model contains assumptions that do not occur in the general theory, so it cannot be part of the latter. For example, a specific theory (or model) of a fluid of a certain kind contains not only the general assumptions of mechanics but also the "constitutive relations" or special laws characterizing that fluid. Again, a theory of the evolution of plants is more specific than the general theory of evolution (on which the former is based), for it contains particular assumptions about the roles of chloroplasts and chlorophyll, roots and seeds, etc. So, it is not a subtheory of the theory of evolution. Likewise a theory of sexual selection is not a subtheory of the theory of natural selection, for it contains concepts—such as those of breeding time, competition for mating partner, and courting—that are absent from the general theory. See Figure 9.5.

In general, we may say that a theory T_1 *specializes* to theory T_2, or that T_2 is an *application* of T_1, if and only if there exists a set A of formulas such that the union of T_1 and A entails T_2. The additional assumptions may be further hypotheses (in particular indicators) or data. (Indicators or "operational definitions" are really hypotheses; they may but need not be included in the specializations or applications of a theory but they must occur in every test of it.) For example, we specialize or apply the theory of partial order when enriching it with (semantic) assumptions concerning the nature of R and $\leq$. And we apply particle mechanics when we specify the system to be a pendulum. In all specializations or applications the original reference class shrinks. That is, the special theories embrace logically the

(b)

Fig. 9.5. (*a*) Theory T_1 is a subtheory of theory T_2. (*b*) Specific theory T_2 is based on theory T_1 and contains set A of assumptions not included in T_1.

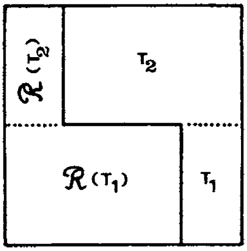

Fig. 9.6. T_2 is a specialization of T_1, and so contains more formulas than T_1 but has a smaller reference class than T_1.

general ones but are referentially included in the latter. I.e. if T_2 is a specialization of application of T_1, then R_2 is included in R_1. See Figure 9.6.

The special theories or models resulting from specialization (or application) can be called *bound models*, for they are attached to general theories. But not all special theories are based in general ones. We call *free models* those that do not result from augmenting the set of assumptions of a theory. (In other words, the totality of formulas of a bound model equals the set of all the consequences of the union of the postulates G of a general theory with the special assumptions A compatible with G, i.e. $P = Cn(G \cup A)$. On the other hand the totality of formulas of a free model is $P = Cn(A)$, for here $G = \varnothing$.)

Whereas in the advanced sciences and technologies most models are bound, in the less advanced ones most of them are free, i.e. they are built from scratch instead of on the basis of general theories. This is particularly the case with the social sciences, where there are no recognized general and valid theories. Needless to say, it takes more imagination to build a free model than to apply a general theory, for in the latter case the existing theory can be used as a scaffolding. Thus no matter how difficult it may be to build a theory of the origin of viri or of fungi, or a theory of the lineage of mammals or of the geographical distribution of plants, the contemporary theoretical biologist can avail himself of general cytological and physiological principles as well as of general theories such as genetics and the theory of evolution. On the other hand the sociologist and the economist have no such guidance. Worse, they are sometimes misguided by theories concerning ghostly entities, such as the free competitive market, or even by ideologies.

The difference between general and specific theories is not always realized or understood. For example, much of the recent work on the foundations and philosophy of classical mechanics takes this to be identical with particle mechanics or reducible to the latter (e.g. Sneed, 1979; Stegmüller, 1976). It ignores continuum mechanics and in particular its constitutive relations (the law statements that characterize kinds of materials). Consequently such studies do not help us understand mechanics or, a fortiori, scientific theories in general. (See Truesdell (1983) for a devastating criticism of such pseudomechanics.) Others criticize the theory of evolution for not making precise predictions, not realizing that extremely general theories, whether in biology or in physics, are not supposed to make predictions unless considerably enriched with special assumptions and data. Thus if we wish to understand, retrodict and predict the evolution of giraffes, we must augument the general theory of evolution with a myriad hypotheses and data concerning the camelids and their presumptive habitats. That is, we must build a (bound) model of giraffes. (For an extremely simple but precise model of evolution see Appendix 1.)

Whether free or bound, the models built in factual science and technology are radically different from those studied by model theory, a branch of logic. (See, e.g. Bell and Slomson, 1969.) The latter are not models of concrete things, such as atomic nuclei and factories, but examples of abstract theories. Thus the natural numbers, together with addition (or multiplication), constitute a model of a semigroup, i.e. they exemplify the concept of a semigroup. Likewise the propositional calculus is a model of Boolean algebra, i.e. propositions satisfy and therefore exemplify the laws of Boolean algebra. This, the *logical* concept of a model, must be sharply distinguished from the *epistemological* concept of a model as a conceptual representation of concrete things of a narrow kind. But, whether logical or epistemological, all such models are conceptual: real things are not models of anything, but instead the objects of modeling. (The statement that the real world is a model of some theory makes sense only in a Platonic ontology.) This terminological remark had to be made in view of the widespread confusion between the two kinds of model introduced by the so-called set-theoretic semantics of science (e.g. Sneed, 1979; Stegmüller, 1976).

We have examined two kinds of inter-theory relation, those of subtheory to theory (e.g. statics to dynamics), and of general theory to specific theory (e.g. group theory to commutative group theory). There are several other inter-theory relations. Let us mention a few of them. *Equivalence*: Two theories have the same composition (set of formulas) but different structures, i.e. they are organized differently—e.g. an undefined notion in one of them is defined in the other, or an axiom in the first is proved in the second. *Example*: the different presentations of the propositional calculus. *Refinement*: One theory constitutes a revision of another—e.g. it adopts a more powerful mathematical formalism, drops certain assumptions and adds others, simplifies some of them and complicates others, etc. *Example*: contemporary classical mechanics *vis-à-vis* classical mechanics. *Reduction*: One theory explains or reduces another—e.g. a black box theory is reduced to, or explained by, a mechanismic one. *Example*: molecular biology explains classical genetics. (We shall study reduction in Ch. 10, Section 3.1.) *Rivalry*: Two theories concerning roughly the same domain are inequivalent because, even though they share some predicates, they relate them differently, hence they explain or predict things differently. *Example*: the information-processing (cognitivist) and the psychobiological theories of vision.

So much for theory structure. We have presented a view that is an elaboration of the standard view adopted by mathematicians and theoretical scientists. This standard view is not accepted by all philosophers. Thus some of them mistake theories for languages, even though a language has no deductive structure and should serve to express mutually incompatible theories; others confuse theories (hypothetico-deductive systems) with hypotheses (single propositions); others try their hand at the alchemical art of dispensing with theoretical concepts in favor of empirical ones; still others, while calling themselves realists, claim that theories are metaphors; finally, others include the applications or specializations of a theory in the theory itself. (See Suppe (Ed.) (1974) for a representative sample of this population.) We shall waste no time with these quaint views for the same reason that we do not take the Flat Earth Society seriously. Those are harmless philosophical myths.

On the other hand we must sound the alarm about a real peril for all theorizing, namely the current computer cult. In fact the overrating of the computer is having extremely harmful effects on mathematics, science and technology alongside its well-known beneficial ones. One is that the general public and the bureaucracy of science feel all the more justified in their contempt for theory as their admiration for The Computer grows. This valuational mistake stems in part from the confusion between theorizing and calculation, and the enormous prestige attained by the latter in connection with space travel and missiles. It is usually overlooked that computation, whether by hand or by computer, involves both theory (e.g.

mechanics) and algorithm (e.g. the infinitesimal calculus), so no computer can replace either. Moreover, when used as calculation auxiliaries computers deliver sheer numbers that make no sense except in the light of some theory. When no theory intervenes in the input or the output of a computer, the operation has no scientific significance. Sometimes it is just a piece of pseudoscience.

A second harmful effect of the computer cult is the growing tendency among investigators to neglect the analysis, improvement, and replacement of existing theories. Indeed, a scientist devoted to computation *uses known theories* instead of examining them or inventing new ones. Not being creative, the computer cannot fill in for the original theorist; and not being critical, it cannot replace the foundations researcher. Because of this emphasis on the application of known theories, what began as the best friend of the theorist is turning against him, and what began as the computer revolution is turning into the computer counter-revolution. (More in Truesdell (1981).)

Thus far we have been concerned only with the structure and content of theories, i.e. we have dealt with the logical and the semantical concepts of a theory. But theories can be viewed in alternative ways as well, in particular methodologically, psychologically, sociologically, and historically. Thus we have at least six different concepts of any factual theory T:

Logical: T is a set of statements,
Sematical: T represents its referents,
Methodological: T helps explain, predict, or design experiments,
Psychological: T is a collection of possible thoughts,
Sociological: T is a product of the social process of inquiry,
Historical: T is a link in a historical process.

Different specialists are likely to emphasize different concepts of theory, and some of them are bound to claim that theirs is the only valid one. In particular, those allergic to mathematics are likely to dismiss the logical concept, and those insensitive to history will ignore the historical concept. However, the six concepts are mutually compatible, not exclusive; moreover, they complement one another. Thus the historian needs to know that a theory is (among other things) a logically organized set of statements rather than an unorganized one, let alone a single statement, for otherwise he will not account for the history of theories proper. And it will not hurt the logician to remember that theories, far from being Platonic ideas, are created, reformed, discarded or forgotten by real people engaged in a historical process. Let us then approach the problem of theory construction.

2. CONSTRUCTION AND REALITY

2.1. *Theory Construction*

How are theories built? What are their building blocks and how are these put together? Are data good theory starters or does one begin with hypotheses? Are there any rules for building theories, so that a machine could be programmed to build them? How about theory reconstruction, in particular axiomatization: are there axiomatization kits? And what is the use of axiomatics anyway? These are some of the problem we shall tackle in the present section.

The building blocks of theories are propositions involving concepts of various degrees of remoteness from ordinary experience. Whereas modest theories are built with ordinary knowledge concepts, ambitious theories are built with either highly refined versions of the former or totally new concepts. Thus the concept of a set refines that of a finite collection, and the concept of a position coordinate that of place. On the other hand the concepts of tautology, vector space, electric field, protein synthesis, and elasticity of demand have no ordinary knowledge antecedents.

Whatever its origin and historical evolution, a concept belonging to a theory may be called *theoretical* if it is either peculiar to the theory or considerably elucidated by it. All of the concepts occurring in logical and mathematical theories are theoretical. And, because all the theories in advanced science and technology contain (usually voluminous) mathematical formalisms (or presuppositions), they contain theoretical concepts galore—in fact infinitely many in the case of any theory presupposing ordinary arithmetic. Some of the concepts of a theory are borrowed from its formal (logical or mathematical) background, whereas others are specific to it. Thus, in the theory of partial order we reviewed in Section 1.2 the concept of implication is taken from logic, whereas the order relation is peculiar to the theory.

The specific or technical concepts of a theory are in turn partitioned into *basic* (or undefined or primitive) and *derived* (or defined). Thus in the theory of partial order " $\leq$" is basic whereas "$<$" is derived. All definitions are intratheoretical statements; more precisely, if explicit they are identities. (Vol. 2, Ch. 10, Section 2.2.) One adds them as needed. Occasionally one needs infinitely many. For example, in elementary number theory every number greater than 0 is defined as the successor of some other number, and so an infinitely long chain of definitions is generated.

The propositions (formulas) in a theory are either premises (postulates), definitions, or consequences of premises or definitions, i.e. theorems. (Recall Section 1.2.) The premises of a formal theory are tentative during the construction period, but cease to be so once the theory has been built and shown to be capable of solving some problems. From here on those premises are stipulations that determine the basic properties of the concepts of the theory: they create them. (Definitions proper, such as "2 equals the successor of 1", are noncreative. But axiomatic definitions, such as that of a partially ordered set, are creative.) The worth of the postulates of a formal theory lies exclusively in their power to create or refine concepts, unify previously scattered formulas, and entail new ones. Any conjectures that may arise in the course of investigating a formal theory are to be proved or disproved. When proved they become incorporated into the theory as theorems, when disproved they are dumped into the dustbin.

Having invented and organized a system of postulates and definitions is important but insufficient to solve any particular problems. To tackle the latter one must enrich that system with subsidiary assumptions. This work of specification or enrichment can be endless: witness the development of group theory, classical mechanics, and quantum mechanics. In all these cases the basic equations are adjoined now one set of subsidiary assumptions, now another, to yield in each case a particular theory capable of handling the given problem or allowing one to pose new problems. Thus in the case of group theory one may add the assumptions that the basic set is finite or else infinite, that the group operation is commutative or anticommutative, and so on. In the case of classical mechanics one may add that the thing of interest is a system of particles or a continuum, that the force is central or noncentral, that the viscosity is low or high, and so forth. And in the case of quantum mechanics one may add that the system is an atom or a molecule, that it is embedded in a magnetic field or an electric field, and so on. In this way intratheoretical progress is made, consisting in constructing special theories (bound models) on the basis of the given general theory. In other cases progress is accomplished by discovering the general theory underlying two or more special and formerly unrelated theories. In still other cases the contribution consists in transforming an untidy theory into an axiomatic system. In all these cases advances are made with only pencil and paper.

The case of factual theories is radically different from that of formal theories. Here every premise that is not a definition is tentative, i.e. a hypothesis not a stipulation. It is supposed to prove its worth, jointly with the other premises, not only by its clarifying, unifying and deductive powers, but also by empirical tests suggesting that it is adequate to facts, i.e. factually true, to some extent. Sometimes the special hypotheses contained in theories are called 'data'—e.g. that a system is composed of so many things of such and such kinds, or that it is confined within such and such boundaries. Actually these are not data but corrigible assumptions which, together with the other premises, sketch the properties of the referent. Data have no place in the foundations of a theory, although every factual theory should make room for them. Thus in the theory of exponential growth in Section 1.2 the initial value $F(0)$ of the property in question, and its relative growth rate k, were left indeterminate, for they are to be determined empirically. Once we get such values we can insert them into the theory and use the latter to calculate, say, the value of F at any desired time t. (I.e. we add to the theory statements of the form "$F(0) = a$" and "$k = b$", where a and b are definite positive numbers.)

There are three reasons for excluding data from the foundations of a theory. One is generality. Thus mechanics is supposed to refer to all possible bodies of a certain kind in all possible (lawful) states of motion. This would not be the case if it contained detailed information about the masses and trajectories of the bodies. The second reason is testability: if a theory contained all the available information it would predict its own evidence and would therefore be untestable. The third reason is predictability: if we could know by sheer experience everything there is to know about things of a kind we would not need theories about them. In sum, the foundations of factual theories do not contain data. They only contain blanks to be filled by data.

Yet there is near consensus among scientists that every factual theory is or ought to be "based on" data such as measurement values. (They have not learned this from their research experience but in the classroom and in textbooks.) But it is not clear what 'based on' means in this context. The consensus view is so ambiguous that it can signify either of the five following theses: factual theories rest on data, they are built out of data, they summarize and extrapolate data, data motivate the construction of theories, or a theory, if true, is supported (confirmed) by data. The last two claims are obviously true. Data, at least those of a new kind, call for explanation, and scientific explanation is best performed with the help of theories. And no theory can be pronounced to be a (sufficiently) true representation of a domain of facts unless it has passed some empirical tests. But the first three claims are false. Let us find out why.

First, as we saw a while ago, data do not belong to the foundation or basis of any theory. This is not a historical accident but a matter of logic. Indeed, every datum is a singular proposition, and singular propositions have no deductive power or, if preferred, they have too much of it, for they point to no hypotheses in particular. More precisely, a datum e implies an arbitrary proposition of the form “If h then e”. (In fact, “$h \Rightarrow e$” is false only in case h is true and e false, which contradicts the assumption that e is true.) Second, most of the interesting properties of things, and all of the essential ones, can be observed or measured only with the help of theories, some of which are involved in the very design of measurement instruments. (For example, a way of measuring the mass of a body is to find its weight and divide the latter by the acceleration of gravity, which in turn is measured with the help of a pendulum and the theory of the pendulum. See Figure 9.7.) Third, no measurement can yield any of the sharp values of any of the

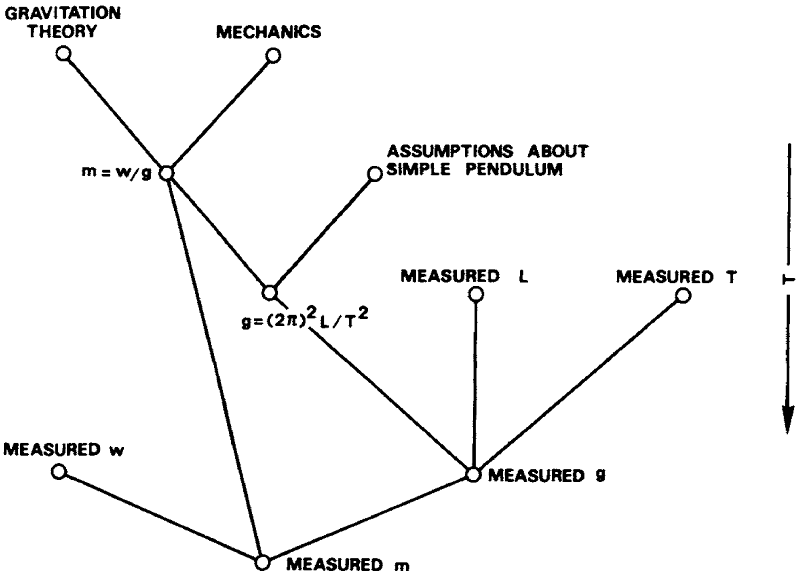

Fig. 9.7. The measurement of mass with the help of a scale (for measuring weight w) and a pendulum (for measuring acceleration of gravity g).

continuous (or piece-wise continuous) functions that occur in all of the advanced factual theories. In particular, the instantaneous values of rates (e.g. speeds) can be calculated but not measured exactly, for measurement yields only averages. (Thus we calculate the rate of change of a property represented by a function F by computing its time derivative, but measurement gives only values of the ratio $\Delta F/\Delta t$ of finite increments.

The problem of whether theories can be built out of data can be approached in the light of the distinction between direct and inverse problems (Ch. 7, Section 4.1). To explain or forecast data with the help of a theory and prior data is a direct problem with a unique (though possibly many-membered) solution. The corresponding inverse problem is: Given a set of data build a theory covering them. Like most inverse problems, this one is indeterminate, both in the sense that data are insufficient, and that there is always more than one theory that explains any given set of data. (Philosophers call this well-known fact "Quine's thesis of indeterminacy of translation".)

Consider the following inverse problem: Given (by observation or by conjecture) the genetic structure of a population at a given time, and assuming a constant environment, find its genetic structure (the distributions of the genes) after a certain number of generations. This is a direct problem that can be solved with the theory of population genetics, which contains precise formulas for simple cases. The inverse problem, of finding such formulas from a study of populations in the wild or in the laboratory, is hopeless, not only because nature does not bother with the simplifying assumptions the theorist is forced to make, but also for the following reason. Most populations in nature have attained a state of equilibrium, i.e. a constant genetic composition, and such equilibrium states can be reached from many different initial states, much as a pebble can reach a given place at the foot of a mountain from many places on the latter. So, the inverse problem is insoluble. Data do not entail theory but may motivate its construction, and theory does not entail data but may help gather them. Only the merger of theory and data can entail further data. Recall Figure 9.7.

If data do not trigger theorizing, what can? Hypotheses can. The theorist usually starts with a handful of more or less disconnected generalizations and, of course, a bag full of mathematical tricks. Some of those generalizations are nothing but empirical generalizations, such as curves that interpolate or extrapolate observational data; others are speculative conjectures. And among the latter some may be mere programmatic conjectures, or schemata to be spelled out, such as "*A* is some function of *B*". These trigger hypotheses may be called the *precursors* of the theory.

Building a system out of precursor hypotheses is not merely a matter of collecting them. They have to be refined and interconnected, possibly by further hypotheses. The refinement may be performed with the help of mathematical tools, and the glue hypotheses may contain concepts not occurring in the precursors. A classical yet often misunderstood example is Newton's creation of classical mechanics. His precursor hypotheses were the kinematical laws conjectured and checked by Galileo, Kepler, Huyghens, and a few others. Newton could not generalize these laws into a general kinematical law because there *is* no such law. What he did was to invent new, dynamical hypotheses containing the new basic concepts of mass and force, to which that of stress was added later on. It turned out that Newton's theory contained not only the precursor hypotheses but also any number of new ones, one for each possible force law, mass distribution, and stress configuration. (Newton's laws of motion are actually schemata that can be specialized by specifying the forces, masses, and stresses.) Likewise the mathematical models that are emerging in neuropsychology contain neurophysiological concepts, such as those of neuronal connectivity and plasticity, and aim at relating and explaining the regularities found by the students of behavior and cognition, as well as many unsuspected ones.

It is difficult to exaggerate the importance of mathematics in the construction of scientific and technological theories. We take mathematics so much for granted nowadays that we sometimes forget the ways in which it helps theory construction. For one thing mathematics offers a huge store of ready made concepts and formulas that, to speak anthropomorphically, are only waiting to be used and interpreted in factual terms. So much so that every factual theory in advanced science or technology is a mathematical formalism together with a factual interpretation of some of its concepts. (See Section 2.2.) For another, mathematics offers a large supply of methods for solving, exactly or approximately, nearly all the problems that are formulated mathematically. So much so that formulating a problem in mathematical terms is usually the hardest stage of a research project in theoretical science, though solving it may be the most time-consuming. (Computers are a great help in solving problems of certain kinds, not in formulating them.) Thirdly, mathematics guarantees exactness and deductive power, and facilitates the gluing and supplementing of the precursor hypotheses of a theory. So much so that the theorist who employs mathematics feels that he is being led by the hand and that his thoughts spread over an entire network that seems not to be his, to the point that he meets unexpected problems and surprising solutions. For a simple mathematical model see Appendix 1.

In the process of building a scientific theory or model with the help of mathematics we can distinguish the following stages:

(i) *survey* of the relevant available knowledge with a vew to finding candidates to precursor hypotheses;
(ii) *invention* of stronger hypotheses, usually containing sophisticated transempirical (nonobservational) concepts, that may entail the precursors;
(iii) *checking* whether the new hypotheses entail the precursor hypotheses or close enough versions of them;
(iv) *mathematization* of the strong hypotheses—often but an aspect of invention, and occasionally requiring the forging of new mathematical ideas;
(v) *investigation of the mathematical problem* with momentary oblivion of the possible factual interpretation—to the point that this stage of research is sometimes taken up by mathematicians;
(vi) *simplifications* facilitating the handling of the mathematical problem or even rendering it tractable;
(vii) *factual interpretation* of some of the results of the previous investigation.

All of these seven steps are equally important. In particular, it is not true that one can always get by without mathematization, or that the essential feature of modeling is simplification. Nonmathematical thinking is clumsy and laborious, inexact and rarely systematic, to the point that purely verbal (i.e. nonmathematical) theories are at best good precursors of mathematical theories. With the help of mathematics we "see" systems, patterns and consequences where none are apparent without it. As for simplification, it is true that it is inherent in theorizing (and also in classification), but it is not more important than invention: the beard must be there before it can be trimmed. And in any case simplicity, if found inconsistent with truth, can be remedied by inventing further concepts or propositions. After all, the historical process has not been that of theoretical simplification but, on the whole, one of progressive complication. Only, such complication is not arbitrary and is not introduced to save some dogma—as is the case with ideological complication—but is motivated by the wish to perfect agreement with fact or a deeper understanding of fact. (See Bunge, 1963.)

In dealing with theories we must avoid several pitfalls. One of them is the very natural attempt to handle new problems with the help of existing theories. While this strategy works in some cases, it is bound to fail in others. Understandably, such conservatism is more likely to succeed in the advanced branches of science and technology. Thus an engineer would be ill advised to try and build a new electrodynamic theory every time he faces a new problem in power transmission or in electromagnetic communication. On the other hand psychologists and philosophers are wrong in insisting that the central nervous system is nothing but a Turing machine, for automata theory does not even contain time, which is essential to account for the variability of neural connections.

A second pitfall to be avoided is that of mathematizing the wrong precursor hypotheses, and embellishing theories that are known to be false or at least are not known to be even approximately true. Contemporary microeconomics, with its powerful mathematics and its slender empirical basis, is a case in point. What is the point of embellishing the neoclassical hypotheses concerning consumer behavior and the way prices are fixed if they are at best untested, at worse at variance with empirical research? Better construct modest econometric models than waste effort studying nonexisting equilibria. (More in Vol. 6.)

A third pitfall is procrastination in starting to theorize for fear that it may be premature. This fear is unjustified, for (*a*) theories, even if false, advance experimental research by suggesting new problems or new ways of approaching known problems; (*b*) knowledge is not properly scientific unless it has a strong theoretical component; (*c*) accumulating empirical information in the absence of theories may prove wasteful, for research that fails to be inspired by theories is bound to yield at best superficial and disconnected data, and at worse irrelevant ones. It is never too soon to start theorizing—and never too late for changing a defective theory for a better one.

Having decided that the time has come to build a theory, can we ask methodology for directions? Is there a logic or technique of theory construction? The answer is in the negative: there are only philosophical fantasies on them. The very idea that original work could be rule-directed is self-contradictory, for originality defies the known rules. (Instead of speculating about the existence of a logic of theory building, we should speculate about the possible neural mechanisms of theory invention, as well as about the social mechanisms that favor or discourage the invention of theories.) Since invention cannot be mechanized, no machine could be programmed to build theories for us. Machines can help once we have created theories and algorithms—e.g. they can help solve some mathematical problems that arise in applying the theories. But even here machines can do only so much. For example, they cannot handle continuity. And their output, namely a bunch of printouts, is far more difficult to interpret than even the least accurate of analytic solutions.

The case of theory reconstruction, or axiomatization, is different: here there is a list of definite do's. (Cf. Bunge, 1973a.) Thus the first step is to investigate the theory to be axiomatized with the aim of spotting the most likely candidates for undefined (primitive) concepts and unproved formulas (postulates)—i.e. the strongest constructs. A second task is to define (implicitly) every undefined notion by means of a set of postulates characterizing both its mathematical form and its factual content if any. (E.g. "F is a piece-wise continuous vector-valued function on the cartesian product of A by B", and "The value of F at $\langle a, b\rangle$, where a is in A and b in B, represents the F-ity of thing a at place b".) Thirdly, we should check whether the proposed system of postulates entails all of the standard theorems in the theory. If not, we should promote some other formula(s) to the axiom rank, or invent an even stronger formula. There are a few other heuristic rules we can use to facilitate axiomatization, but none of them guides the creation of a new theory *ab initio*. In this task only other people, in particular mathematicians, can help the creative theorist.

(It may be objected that modern metamathematics has shown the limits of axiomatizability, particularly with regard to completeness and decidability. For example, the following result has been proved for an arbitrary theory T formalized within the first order predicate calculus with identity: *If T is complete, then T is not axiomatizable iff T is undecidable*: see Tarski *et al.* (1953). Since the vast majority of theories are undecidable, it would seem that axiomatization is the exception rather than the rule. This is not true, for the theorem holds for *complete* theories, and in science and technology there are no complete theories. Moreover, in these fields we have no use for complete theories, as a theory can be applied only if it is *incomplete*, for only then can it be enriched, without contradiction, with subsidiary hypotheses and data. So, the above metamathematical result has no bearing on the axiomatizability of factual theories.)

Should it be asked what the value of axiomatics is, we could answer with another question, namely 'What is the value of cleanliness and tidiness?' In axiomatizing a theory we are bound to discover gaps or inconsistencies, refine concepts, overhaul the mathematical formalism, and reorganize the formulas in a clearer and more reasonable fashion. In the process we may discover new theorems or discover that some formulas that used to be taken for theorems are not really part of the theory. We may facilitate the spotting of the deficient presuppositions or hypotheses to be corrected. We may establish that certain formulas are definitions, and thus save the experimentalist the trouble of trying to test them. We may dispel any doubts concerning the genuine referents of the theory. Also, an axiomatized theory is easier to recall and therefore use. Finally, axiomatization renders a deep and cogent philosophical analysis of theories possible.

Unfortunately a romantic wind is blowing in philosophy once again. Romantics abhor formalization and even analysis, preferring to make sweeping, global, vague, and sometimes derogatory assertions about theories, theorists, and society. There seem to be several causes for this revolt. One is that it is but one aspect of the general movement against science and technology that accompanies both the revival of religious fundamentalism and the youthful rebellion against the establishment. Another is that most of the philosophical formalizations in the past, notably those proposed by Carnap and Reichenbach, turned out to be unfaithful to science and philosophically unilluminating. A third cause is that it is far easier to revolt against formalism than to learn it. This revolt is unreasonable. If one type of formalization does not work, e.g. because it bears on cartoons of scientific theories, or on trivial problems, then one should try a better one. And if one dislikes formalism, one should stay clear of advanced science and technology, which carry mathematics in their very bones.

To conclude, there is no method for building theories other than a command of the basic facts, the founder generalizations, and some mathematical tools. The so-called inductive method does not deliver theories because data collection itself is done in the light of some conjecture or other. Nor does the so-called deductive method yield theories, for it works only where the initial hypotheses have already been conceived. Theory construction is not a rule-directed process but an original brain process to be studied by psychology and social science, not by logic. Such an empirical study of theory construction must pay particular attention to the background knowledge and values of the theorist, to the way he sees the world and our knowledge of it. (See Holton (1973) for the importance of general guiding principles in theorizing.)

2.2. *Theory and Reality*

We have called a theory *formal* if all its referents are constructs, and *factual* otherwise (Section 1.2). Formal theories are then, by definition, unrelated to reality—except of course that they are invented, learned, and used by real beings. On the other hand factual theories are doubly related to reality: semantically and methodologically. In fact they *refer* to certified or putatively real things, and they are *tested* by confrontation with experience, which is a part of reality. In this section we shall be concerned with the semantical relation of representation, leaving the methodological relation of confirmation for Ch. 12, Section 2.1.

Because a factual theory is about certified or putatively real objects, it is more than a formalism: it also includes propositions telling us what refers to what and what represents what. We call these propositions *semantic assumptions*; in the literature they are usually misnamed 'correspondence rules' or even 'operational definitions'. In our view semantic assumptions are corrigible hypotheses, not rules or definitions: we assume them and then check whether the theory containing them passes some empirical tests. If it does, then the system composed of the formalism and the semantic assumptions is pronounced true until further notice. Otherwise we introduce changes in the formalism or the semantic assumption—or abandon the theory altogether. For example, a mathematical model originally designed to account for the propagation of a contagious disease may not do this job but may instead represent adequately the propagation of rumors: the formalism is kept and only the semantic assumptions are modified. See Appendix 2 for an example.

Every semantic assumption is an *interpretation*, i.e. a formula of the form "Concept X stands for (or represents) Y". Some interpretations assign constructs to constructs, others to factual items. We call the former *formal*, the latter *factual* interpretations. Thus the basic (undefined) concepts of the theory of partial order (Section 1.2) can be interpreted as follows:

$$\rho(R) = \textit{The set of natural numbers},$$
$$\rho(\leq) = \textit{Less than or equal to}.$$

This interpretation yields a *model* or example of the abstract theory of partial order: i.e. the formulas of the latter are satisfied under that interpretation. This model does not represent any facts: its semantic assumptions relate concepts to concepts. If, on the other hand, we set

$$\rho(R) = \textit{Collection of lamp posts along a highway},$$
$$\rho(\leq) = \textit{To the left of},$$

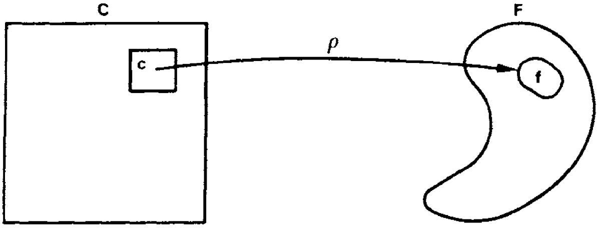

Fig. 9.8 The representation function ρ assigns a subset c of the set C of constructs a subset f of the collection F of factual items.

we produce a model of a collection of factual items. We say that the factual interpretation has produced a *factual model*, i.e. a theory representing a collection of factual items: See Figure 9.8.

The expression 'factual model' is ambiguous, for it signifies an example of an abstract theory and also a model of some factual domain. In the above case the factual interpretation of R and $\leq$ produced a model that is both. Likewise a linguistic interpretation of the theory of semigroups, and an interpretation of Boolean algebra in terms of switching circuits, yield models in both senses. However, not every factual model is of this kind. Most models in science and technology involve mathematical formalisms that have already been interpreted in mathematical terms—e.g. not abstract geometry but Euclidean geometry, not the general theory of functional spaces but the theory of Hilbert spaces. See Figure 9.9. However, the essential point is that factual models, unlike formal models, represent certified or putatively real factual items—material things, their properties, and changes in the latter. Because of this factual reference they must be tested not only conceptually but also empirically.

(Whether conceptual or factual, an interpretation may be construed as a function $\rho: 2^C \rightarrow 2^D$ assigning to every subset of a set C of constructs a subset of a different collection D. If D is taken to be a set of nonabstract but still conceptual items, the interpretation is called *formal*, as when we assign to every subset of C a set of natural numbers, or of points on a sphere, or of real valued functions. Model theory, or the semantics of mathematics, handles only formal interpretations. On the other hand the semantics in Vols. 1 and 2 of this *Treatise* focuses on the case when D is a set of factual items, such as things, properties of things, or events in things. In this case ρ is called a *factual* interpretation, and the corresponding model a *factual* one. Actually factual interpretations are *partial* rather than full functions, for they do not assign to every construct a collection of factual items. Thus a theory presupposing the infinitesimal calculus may contain all the infinitely

(*b*) Conceptual models within factual science and technology: whereas some result from interpreting abstract theories, the great majority result from superimposing factual semantic assumptions on mathematical formalisms that have already been interpreted in mathematical terms—e.g. where sets are not abstract or generic but are composed of specific objects such as real numbers or points in a Euclidean three-space.

many derivatives of every function occurring in the theory, but only the first few derivatives are assigned factual interpretations, e.g. as velocities or accelerations.)

(In view of the preceding we may now characterize theories in a fuller way. An *abstract theory* is, as stated in Section 1.2, merely a logically organized context, and so characterizable as a quadruple $\mathcal{T}_a = \langle P, Q, R, \vdash \rangle$. On the other hand an *interpreted theory* is a logically organized context some components of which are assigned an interpretation, i.e. $\mathcal{T}_i = \langle P, Q, R, \vdash, \rho \rangle$, where $\rho: 2^C \rightarrow 2^R$, and $C = P \cup Q$. In particular, a factually interpreted theory, or *factual theory* for short, is an interpreted theory some components of which are assigned a factual interpretation, i.e. $\mathcal{T}_f = \langle P, Q, R, F, \vdash, \rho \rangle$, where now R includes a nonempty collection F of factual items, and $D = F$, so that $\rho: 2^C \rightarrow 2^F$ is a partial function assigning factual items to some constructs in $C = P \cup Q$.)

The notion of factual interpretation allows us to analyze the set P of propositions of a factual theory $\mathcal{T}_f$. To simplify the discussion, assume that the theory has been axiomatized. Then the set of its postulates is divided into two disjoint subsets: the set M of all *mathematical* axioms, and the set S of all *semantic* assumptions. Every mathematical assumption is a formula of some mathematical theory, and every semantic assumption is of either of the following types:

For sets: "Set A equals such and such kind of (presumably) real entities."

For functions: "Function F represents such and such property of entities of kind K."

A first consequence is that the totality P of propositions of $\mathscr{T}_f$ equals the set of consequences of the union of M and S, i.e. $P = Cn\,(M \cup S)$. A second consequence is that the set P of formulas of $\mathscr{T}_f$ is divided into two disjoint subsets: (*a*) the set P_m of purely mathematical formulas, i.e. those specifying formal properties of the predicates, and (*b*) the set P_f of formulas that are assigned a factual interpretation by virtue of the factual semantic assumptions of the theory. For example,the propositions "A is an algebra of sets" and "F is twice differentiable" are purely mathematical formulas. On the other hand the law statements and the definitions containing factually meaningful concepts, such as the definition of zero centigrade, belong to the set P_f of factually meaningful formulas.

Let us insist that the semantic assumptions are necessary components of all factual theories because a mathematical concept can be interpreted in alternative ways or in none. For example, an increasing function may represent an expanding volume in one theory and a growing population in another. Also, the semantic assumptions are not conventions like the definitions: they are hypotheses and as such they may prove false. For example, in physics an interpretation of an equation as describing a process is said to be 'unphysical' if it allows an event to occur before its cause; and in biology a semantic assumption interpreting a certain function as the total population of an ecosystem is dubbed 'unbiological' if that function takes on negative values.

That the semantic assumptions are hypotheses does not mean that they can be checked empirically in isolation from the formulas they are attached to. What are testable are these formulas together with their factual interpretation or, rather, the factually interpreted formulas. For example, the formula "$y = ax + 1$", where every symbol designates a positive real number, is not empirically testable. On the other hand the following is: "$y = ax + 1$, where 'y' represents the ratio of lengths of a metal bar at temperatures x and 0, and a is the expansion coefficient of that particular metal".

Any given thing can be represented by different theories. This is not a datum but an epistemological hypothesis confirmed but not proved by historical research. It is an optimistic hypothesis that encourages theorizing and moreover it is an irrefutable hypothesis. Indeed, were we to face things of some kind that appeared to resist theoretical modeling we would rather blame our own incompetence than the things themselves, and we would hope that others should succeed where we have failed.

Factual theories represent their referents but are not perfect pictures of them. They are not pictures at all but symbolic constructions bearing no resemblance to the objects they represent. (Boltzmann wrote that the relation of theories to reality is like that of letters to spoken words, and Einstein that it resembles the relation between numerals and coats in the cloak room.) Nor can theoretical representations be perfectly faithful: they are at best approximately true. Hence naive realism is just as wrong as conventionalism. Critical realism is the ticket.

The different theories representing things of a given kind are not necessarily equivalent: some may be deeper or truer than others. For example, consider the following sequence of models of the terrestrial atmosphere that have been considered historically, and are still being studied:

1. Flat earth, homogeneous film of dry air, no radiation.
2. Round earth, homogeneous film of dry air, no radiation.
3. Flat earth, different strata of dry air, no radiation.
4. Round earth, same.
5. Flat earth, strata of moist air, no radiation.
6. Round earth, same.
7. Flat earth, each stratum of moist air divided into homogeneous parallelepipeds, no radiation.
8. Round earth, same.
9. Flat earth, same plus radiation.
10. Round earth, same.

Each model is more realistic than the preceding in at least one respect, and the last is the most realistic (the truest) of all. But even the first model, though very coarse, has some use, for it allows for winds—although, without radiation, it cannot explain them, and without moisture, it makes no room for precipitation.

This concludes our accout of the semantics of factual theories. (For a more detailed treatment see Vols. 1 and 2.) Our account differs radically from the view commonly held by mathematicians or philosophers, which neglects the factual semantic assumptions. One such popular view is *Pythagoreanism*, according to which things *are* constructs instead of being represented by constructs. Thus some writers state that a particle is an oriented one-manifold, an electromagnetic field a tensor field, and in general a physical system "a set of individuals together with numerical functions on these individuals" (Sneed, 1979). This view is incapable of distinguishing between mathematics and factual science. It does not explain how an unchanging construct, such as a tensor field, can be identical to a changing thing, such as an electromagnetic wave. Besides, it is contradictory, for it identifies a given construct now with one thing, now with another, instead of stating that the construct represents one thing in one theory, and another thing in another.

A related view is *formalism*, according to which model theory, i.e. the semantics of mathematics, suffices to analyze factual theories (Sneed, 1979; Stegmüller, 1976). The upholders of this view have probably been misled by the ambiguity of the term 'model', which in metamathematics designates an example of an abstract theory, whereas in science and technology it designates a specific theory (Section 1.2). Consequently they ignore the concepts of reference and representation, central to the semantics of factual theories, and they cannot explain why factual theories cannot be validated or invalidated by purely mathematical considerations. (For further criticisms of Pythagoreanism and formalism see Vol. 2, Ch. 6, Section 3.)

Finally there is *operationism*, or the doctrine that factual theories are mathematical formalisms enriched with operational "definitions", i.e. descriptions of the way the properties represented by the theory are measured. This view is far closer to the truth than the two previous views, but it confuses matters of reference and representation with questions of test. It ignores that one and the same property may, in principle, be measured by different methods. (For further criticisms of operationism see Vol. 1, Ch. 5, Section 3.4, and Bunge, 1973a, Ch. 1.)

In contrast to the above views ours is realist and it has been incorporated into the axiomatization of several basic physical theories (Bunge, 1967b).

3. CONVENTION AND LAW

3.1. *Convention*

There are several kinds of convention, and every theory contains at least conventions on nomenclature. Some conventions, like counting the negative numbers on the left side of an axis, are mere customs (that might not have been adopted if we all were left-handed). Others, like definitions, are time-saving and clarity-gaining devices. Some conventions are dispensable and all are replaceable. Also, some conventions are more useful than others. For example, in daily life the meter is handier than either the fermi, convenient in atomic physics, or the light year, convenient in astronomy.

We shall study conventions of the following kinds: notational, definitions, conventions about scales, and simplifying assumptions. *Notational conventions* assign nonlinguistic objects to signs. They are of two kinds: designation rules and denotation rules (Vol. 1, Ch. 1). A *designation rule*, such as "'$\mathbb{N}$' designates the set of natural numbers", assigns a construct to a symbol. (Nominalists do not need designation rules and they have no concept and no name for that which remains invariant under changes of name.) And a *denotation rule*, such as "'W' denotes the direction in which sunset occurs", assigns a factual item to a symbol. Similar conventions are those concerning the positive direction of rotations, the sign of electric charges, and the choice of the initial and final stage of a process. Every single notational convention is replaceable, though perhaps at the risk of confusion. But every explicit context, in particular every theory, should contain a set of notational conventions—unless they are notorious.

A *definition* is a horse of a different color: it stipulates the identity of two concepts or of their symbols. Thus we may define "positron" as "positive electron" and "1" as the successor of 0 in the set of natural numbers. Such identities are adopted by convention, whereas others, such as "For all real numbers $x, (-x)^2 = x^2$", are provable. The specific difference between a definition and an identity is then that the former is stipulated. Such difference is strictly methodological. On the other hand the identities "Heat = Kinetic energy of randomly moving atoms or molecules", "Gene = Segment of DNA molecule", and "Mental state = State of a plastic neural system in a living brain", are hypotheses to be justified empirically. They state identities of factual items, not of concepts; they state the synonymy of different expressions.

Whether or not a formula is a definition depends on the context in which it occurs. Thus whereas in elementary mechanics forces are undefined and linear momenta defined, in Hamiltonian dynamics forces are defined and linear momenta are primitive. And depending on the context we may postulate or prove the existence of other minds. (In principle it can be proved from the basic similarity of all human brains.) The contextuality of definitions is just a particular case of the contextuality of concepts. Thus the concept of mammal does not occur in pure mathematics, and that of creation out of nothing is out of every scientific context. Only mathematical and philosophical concepts can cross all disciplinary borders.

That definitions are conventions does not mean that they are wholly arbitrary. In a well-organized context the place of a definition cannot be shifted without reorganizing the entire system, and the defined concepts cannot exchange places with the defining ones. For example, numbers can be defined in terms of sets but not conversely. Likewise, "process" can be defined in terms of "thing" but—*pace* Whitehead and his followers—the converse is impossible. (Indeed the very notion of a process, or sequence of states in a thing, involves some concept of a thing. Therefore the definition of "thing" as "a bundle of processes" is circular.) Given a choice of undefined concepts, the strongest ones are preferable, and the defined ones cannot be introduced haphazardly but in an orderly fashion. (Thus the definition of state of a thing presupposes the concepts of thing and of property of a thing.) Moreover, definitions are sometimes backed by axioms or theorems, so they cannot be introduced until such formulas have been stated. Thus the notion of an inertial reference frame is definable in terms of equations of motion, or of field equations, which in turn presuppose the general concept of a reference frame, as well as the concepts of space, time, and much else.

Definitions relate concepts but this does not mean that they lack factual reference or factual presuppositions. For example, the definition of "100° C" as the (same as) the boiling point of pure water at sea level has a factual content: it refers to water. And the definition of "machine" as "artifact for transforming energy of some kind to some purpose" presupposes the law of conservation of energy. Indeed a device alleged to create or annihilate energy would not be called a machine.

Even if a definition has an external reference, it does not introduce new knowledge and cannot take the place of a hypothesis. (This does not hold for axiomatic definitions, which are creative and, in the case of science, are systems of hypotheses.) In particular, a definition belonging to a theory in pure mathematics does not describe any processes in the real world, not even if interpreted in factual terms. (This is ignored by the Bayesian school of epistemology, according to which Bayes' theorem represents the way we learn from experience. This is false, for the theorem is an immediate consequence of the definition of conditional probability.)

Since definitions define only concepts, they cannot define things. This must be stressed because some philosophers believe that the referents of factual theories can be defined the same way concepts are defined, e.g. in terms of a system of equations. What such a system does is to *describe* its referents not to define them. What is true is that a theory may help *identify* factual items as members of a class. For example, Newton's mechanics, together with certain measurements, helps us identify bodies, genetics genes, and so on. In short, an adequate (sufficiently true) theory (*a*) describes its referents, (*b*) defines some of its own concepts, and (*c*) is a criterion for identifying (not defining) its referents. On the other hand most definitions are not utilizable as criteria. Thus a definition of consistency is no criterion for proving or disproving the consistency of a theory, and a definition of truth does not suffice to assign truth values.

All factual theories, and all measurements, involve *units*: of length, time, mass, etc. Units are conventional and they are involved in the very characterization of magnitudes such as physical quantities. Thus when giving the value of the mass of a body b relative to a reference frame f, it is essential to mention the unit u in which it has been measured or computed. In short, such a datum or assumption has the form "$M(b,f,u) = m$", where m is a positive real number. (In general, the property mass is represented by a function of the form $M: B \times F \times U_M \to \mathbb{R}^+$, where B is the set of all bodies, F that of all reference frames, and U_M that of all conceivable mass units, whereas $\mathbb{R}^+$ is the set of positive real numbers. See Bunge (1971).)

The meter, the second and the kilogram can be taken as fundamental units; the micron, the year and the gram as derived units. Units are conventional but not wholly arbitrary. Thus the second, or more precisely the mean solar second, is defined as 1/86,400 mean solar day, which in turn results from astronomical observations and calculations. The fundamental units are materialized as standards, which are reproducible in any well equipped laboratory. And such standards, far from being arbitrary, are chosen because of their accuracy, stability and reproducibility. A good example is the atomic length standard, defined as the wavelength of a certain sharp spectral line that is easy to prepare and measure, and that has a known theoretical description (namely as the result of a certain atomic transition).

A full homogeneous scale is equipped not only with a unit but also with a starting point or *zero*. The absolute or Kelvin zero of temperature is one example. The year 1 A.D. is another such conventional point of departure—the number 0 having been unknown to the makers of the Western calendar. Such choices may look natural and in a way they are, but they are conventional. Thus we could shift the zero of temperature below its current position by an arbitrary amount. However, the additional stretch would have no use, since atomic and molecular motion cease at the universally accepted absolute zero. (As a consequence we would have to subtract a certain constant from all the energy values.)

Next in our list of conventions come *simplifying assumptions*. All except fundamental theories contain some simplifying assumptions. For example, in a certain calculation or measurement we may pretend that the value of *pi* is 3.14; that the system of interest has no internal structure, or is perfectly well isolated, or has only the properties we happen to know; that certain discontinuous variables, such as population, are continuous—or conversely; that brain functions are not affected by social circumstances; that unemployment or inflation has a single cause, etc. All such simplifying assumptions are introduced to expedite modeling or inference, or even to make them possible. They are white lies, for they serve the search for truth. They become black lies when presented as truths or when we keep them even after having been shown to be wide of the mark—as is nowadays the case with the assumption of perfect competition, still at the heart of most economic models.

In sum, all theories contain conventions and, paradoxically, factual theories contain the most. The epistemological moral is obvious: Although factual theories may represent their referents in a fairly true manner, such representations are not pictures or copies.

3.2. *Law*

Man is a compulsive pattern seeker. We abhor the idea of chaos and tend to see regularity even where there is none. Thus, unless we are familiar with probability, we may feel tempted to commit the gambler's fallacy, i.e. to expect that a streak of bad luck will be compensated for by one of good luck, and conversely. We expect order and this is why we look for it. But order is seldom perceptible: the phenomenal world, unlike the real world, is chaotic. Therefore pattern must be either hypothesized or imposed. We hypothesize pattern when we hazard a hypothesis about some constancy or some trend; we impose order when we enforce a rule of action, i.e. compel things to fall into step.

Let us examine the ideas of pattern, trend, empirical regularity, law, and rule. Any stable or reproducible configuration of objects of some kind may be called a *pattern* even if it is the outcome of chance. *Examples*: a string of pebbles left on the sand by the tide, a finite sequence of tones, a behavior pattern. Common to all these instances are order and stability (or repeatability or reproducibility). Every pattern is some order in some collection of objects, and can thus be represented as a structured set. The structure is a set of relations, possibly functions. The converse if false: even a totally chaotic (but finite) set of points on a plane can be represented by a function. Only, such function will not belong to a family, will not be continuous, will not solve an equation, etc.: it will be an *ad hoc* or stray function. More on this below.

Patterns are stable for a while but need not be eternal. Internal tensions among the members of a system, or environmental changes, may end up in pattern changes. Thus a teacher, trainer or experimenter can teach an animal to adopt new behavior patterns by rewarding actions of certain kinds. But he can just as easily extinguish the newly acquired behavior pattern by negative reinforcement. In either case the teacher forces a pattern change, or repatterning. (He does so with the help of certain learning laws.) In the case of biosystems and sociosystems repatterning can occur without change in species. Thus a biopopulation occupying a new territory, and doing well in it, does not change species immediately. Likewise a social system surviving a drastic change, such as revolution or war, may still be what it used to be, e.g. a production center or a school. On the other hand, in the case of physical and chemical systems repatterning is always accompanied by changes in kind or species.

One of the most interesting problems is that of the emergence of pattern from the interplay of initially independent, hence randomly behaving, entities. For example, dust is distributed irregularly throughout the universe, but gravitational attraction clumps it; if several penduli are suspended from an elastic bar, they end up by oscillating synchronically regardless of their initial positions; any piece of cast metal is a random agglomeration of grains of irregular bulks and shapes, but when drawn into a wire or rolled out into a sheet they tend to adopt a common orientation; genic mutations and recombinations are random, but the environment makes certain uniform demands and thus produces some order; likewise the actions of persons are constrained by nature and society, and thus fall into patterns. In all such cases the scientific problem is to explain the emergence of pattern, or the repatterning, in terms of laws and circumstances. And the technological problem is to favor, channel, or prevent processes of pattern emergence and repatterning.

A pattern is called a *trend* when it is a uniform sequence of states of, or events in, a system. Thus the expansion of the universe, and the increase in the prices of most commodities over the past decade, are trends. So are the increasing effectiveness of the hands along the evolution of primates, the steady increase of the total human population since the industrial revolution, the increasing literacy and the rising life expectancy in the Third World, and the increasing lethality of weapons.

Trends are stable while they last. They can stop or even reverse, particularly if the events concerned are brought under human control. Thus at the time of writing it is conceivable that, at some point in time, the universe will start contracting and prices will start falling. The uncovering of trends is an important task in every discipline. It is often the work of educated intuition, and sometimes the result of applying certain statistical techniques. (The whole of econometrics is an effort to discover and represent economic trends.) But we should not rest content with knowing about trends: we should try and explain them in terms of laws and circumstances.

Trends are not laws but they are often confused with laws in the life and social sciences. A good example is the so-called Lartet law, according to which the brains of mammals and birds have increased steadily in relative size along evolution. This is a typical trend, so much so that most of the species to which it applies have become extinct. Or take Marx's objective of discovering what he called "the laws of motion of the capitalist society". He did not attain it, but he did discover a number of trends or short term tendencies. Some of them, such as the increasing concentration of capital, are still in force; others, such as the increasing pauperization of the working class, have been reversed in the industrialized countries. (More on the difference between trends and laws in Popper (1957) and Bunge (1967a).)

Next in line come the empirical generalizations occurring in all branches of factual knowledge. A formula may be called an *empirical generalization* if it is a summary of data or an inductive generalization from data. In science and technology the typical empirical generalization is the smooth curve fitting a finite set of observational or experimental data: Figure 9.10. The empirical generalizations of this type are full fledged hypotheses, not data, for they interpolate between data: they concern not only actuals but also possibles. Consequently they are less, not more certain than the data they cover—so much so that every set of data, being finite, can be covered by infinitely many smooth curves passing near them. True, in the absence of a theory we usually choose the simplest such curves. However, simplicity is convention, not law. Indeed further research may well, and often does,

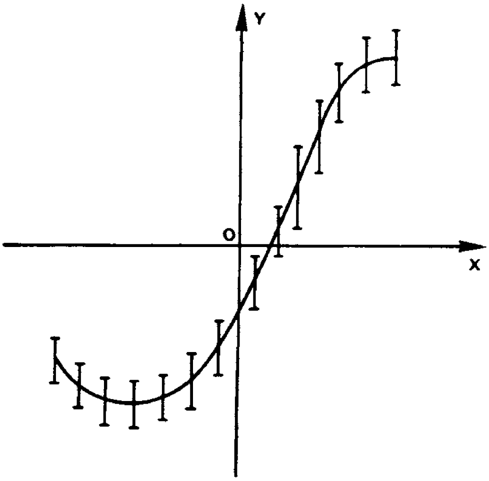

Fig. 9.10. One of the infinitely many possible curves passing through a set of data. The vertical segments, possibly unequal, represent the errors of observation.

refute the simplest hypothesis, forcing us to adopt a more complicated one exhibiting the fine structure of the factual domain in question. See Figure 9.11.

An empirical generalization is supported only by the data that suggested it: it is a stray not a systemic hypothesis. Should new unfavorable data appear, we will be forced to give it up, for we have nothing else to fall back on. If the generalization has been obtained by using a standard in-

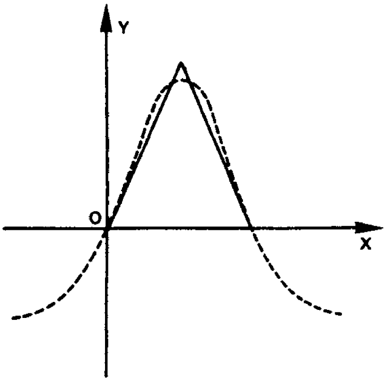

Fig. 9.11 Data suggest full line. Theoretical investigation suggests dotted line.

terpolation or curve fitting technique, it can easily be corrected by changing the values of some of the parameters occurring in it. But this methodological advantage has a high semantic price, for such parameters have seldom a factual meaning. So, paradoxically, empirical generalizations involve concepts without real counterparts. As we shall see in a moment, this is in sharp contrast with fundamental laws.

Laws are patterns of a very special kind: they are systemic, not stray, and they do not change unless the things that satisfy or "obey" them are metamorphosed, i.e. change into things of a different kind. The laws of constructs are propositions, such as the associative and the commutative laws for the addition of numbers. On the other hand the laws of concrete or material things are properties of the latter—and not just any properties but their essential properties. These objective patterns, like the trends, are representable by propositions. We call them *law statements*. This difference, nonexistent in an idealist epistemology but central to a realistic one, is a particular case of the fact-construct difference. In every case a given factual item, be it state, event or pattern, is representable by alternative propositions, some truer than others.

A law statement is a hypothesis asserting that every thing of some kind has a certain property. The following are typical, though by no means exhaustive, forms of law statements found in science and technology. (*a*) "If x is a thing of kind K, and x possesses property P at any given time, then x conserves P at any other time". (*b*) "Every thing possessing property P possesses also property Q". (*c*) "All events of kind E have the same probability p". (*d*) "If x is a thing of kind A, and x undergoes a change of type P, x becomes a thing of kind B". (*e*) "The probability distribution of property P of things of kind K changes in the course of time according to such and such formula". (*f*) "Properties F and G of every thing of kind K are lawfully related to one another". (The mathematical form of this programmatic hypothesis is as follows. Let $f: A \rightarrow B$ and $g: A \rightarrow B$ be functions representing the properties F and G respectively. Then F and G are *lawfully related* if, and only if, there is a third function $h: A \rightarrow B$, representing another property of things of the same kind, such that g is the composition of h and f, i.e. $g = h \circ f$. See Figure 9.12.)

Law statements have occasionally been construed as prohibitions (Popper, 1959). Actually law statements tell us what is possible, from which we infer what is not. What happens is that, in certain popular versions, a handful of law statements are presented as statements to the effect that certain facts are impossible. Here are three well-known examples. (*a*) The

$$\begin{tikzcd}
a \arrow[r, mapsto, "f"] \arrow[dr, mapsto, "g = h \cdot f"'] & f(a) \arrow[d, mapsto, "h"] \\
 & g(a)
\end{tikzcd}$$

Fig. 9.12. Functions f and g represent properties of thing a. They are lawfully related if there is a third function h, which also represents a property of a, and such that its composition with f equals g.

principle of conservation of energy is sometimes translated into pragmatic terms (i.e. transformed into a nomopragmatic statement) for technological purposes, namely thus: "It is impossible to construct a perpetual motion machine of the first kind". But the original principle is affirmative, nonmodal, and refers to closed systems in general, not necessarily machines. (*b*) Pauli's exclusion principle states that the different components of a microsystem are in different states, or that the probability of their being in the same state is zero. But it can be reformulated in a more intuitive way, as "No two components of the same microsystem can be in the same state". (*c*) The competitive exclusion principle of ecology was originally formulated as "No two species can occupy exactly the same niche", or "Complete competitors cannot exist". A more correct (and more easily formalizable) formulation is: "Every species has its own peculiar niche" (or "There is a bijection between the set of species and the set of niches"). In short, law statements are not prohibitions but they can be used as premises for deriving prohibitions. By delimiting the set of lawfully possible events we *eo ipso* characterize the set of conceivable but factually impossible events.

The specific differences between a law statement and any other factual statement are generality, systemicity, and confirmation. More precisely, we adopt the following definition (Bunge, 1967a). A factual statement in a theory is a *law statement* if, and only if, (*a*) it is general in some respect (i.e. refers to every single member of a species, or extends over an entire region of spacetime), and (*b*) it has been satisfactorily confirmed (for the time being). New data may restrict the domain of truth of a law statement. They may show that the latter holds only between certain bounds of certain variables; or, on the contrary, they may show that the law statement holds beyond the domain originally postulated. And the data may also refute the statement, in which case it is demoted from the rank of law statement, and the whole theory containing it is put in jeopardy.

This suffices to show how different laws are from definitions, with which they are sometimes confused. For example, Mach and his followers regarded Newton's second law of motion as a definition of "force". This is a mistake, for (*a*) there are a number of distinct force laws, which must be hypothesized separately from the law of motion, and (*b*) the latter, in conjunction with a definite force law, is empirically testable—and moreover it has been found false in the very small as well as in the very large. (For a criticism of Mach's attempt to define "force" and "mass" see Bunge (1966).)

The most precise representation of a law is with the help of functions. But not every function qualifies. Thus the function f that maps the set $\{a, b, c\}$ into the set $\{d, e\}$ in such a way that $f(a) = d$, $f(b) = e$, and $f(c) = d$, is a stray or *ad hoc* function that represents no intrinsic structure of its domain. We shall call a function *systemic* if it is the object of a theory and belongs to a system or family of functions, i.e. a set whose members are mutually related in precise ways—e.g. by recursion formulas. Otherwise the function will be said to be *stray*. For example, the trigonometric, spherical, cylindrical and hypergeometric functions form systems. The concept of a systemic function allows us to define lawfulness in this way: A set of factual items (states, events or processes) is *lawful* if it is representable by, or with the help of, systemic functions.

Probabilities are systemic for they are subject to the theory of probability. They occur in all *probabilistic* (or *stochastic*) law statements. Notwithstanding the opinion of distinguished philosophers (notably Nagel (1961) and Hempel (1962)) probabilistic law statements are universal in form and scope. For example a velocity distribution law states that, for *all* systems of a certain kind (e.g. molecules in a gas, or cars in dense traffic), the probability of an individual component having a velocity comprised between v and $v + \Delta v$ equals $p(v). \Delta v$, where p is the probability distribution characteristic of the system. On the other hand statistical generalizations, which are empirical, are not universal. In fact, a typical statistical generalization is of the type "f percent of A's are B's". Every such generalization concerns a population as a whole, whereas the corresponding probabilistic laws concern every individual of a given population.

Randomness is not the opposite of lawfulness but one type of it. Thus every outcome of a coin flipping experiment has a definite probability. A sequence of events can be said to be *random* if every event in it has a definite probability; otherwise the sequence is either chaotic or causal. (This is not the standard definition of randomness—but then there is no standard definition.) Randomness can exist objectively, as in the case of atomic and molecular events and of genic mutations; or it can be manufactured, as in the case of randomization and random sampling. Interestingly, random sampling can be used to uncover order, not only in factual science and technology but also in mathematics. This is the case with the Monte Carlo method for solving certain numerical problems. (*Example*: Suppose the problem is to compute the area of a region E of the plane included in the unit square. To do so select at random n points from the unit square, determine their positions x_i, and find out whether they belong to the given region E. That is, assign a value to the characteristic function χ_E of the set E to each sampled point. The Monte Carlo approximation is: Area of $E \cong (1/n) \sum_{i=1}^{n} \chi_E(x_i)$).

Laws, whether or not probabilistic, should not be mistaken for processes, in particular trajectories, life histories, and histories. Thus it is false that every one of us has his own laws: we all share a number of laws but differ in our circumstances, hence in our life histories. Every process can be analyzed into laws and circumstances. And every set of laws is compatible with many different processes, as many as different sets of circumstances. The particular circumstances are representable in the law statements by assigning special values to the parameters occurring in them or in their logical consequences. Thus there is presumably a single law of biological growth, but every pair $\langle$species, environment$\rangle$ is characterized by its own parameters. In other words, a single law covers an entire bundle of trajectories or histories. See Figure 9.13.

Given laws and data we can infer (tentatively) the corresponding processes. The inverse problem, to infer laws from descriptions of processes, is logically impossible because every law encompasses, in principle, infinitely many possible processes. In other words, law statements cannot be inferred from a knowledge of processes or histories. Hence they must be hypothesized—and checked. Far from being inferred, law statements are inference tools. For example, a recursion formula may allow one to infer the nth member of a family of functions from a knowledge of the $(n-1)$th or the $(n+1)$th or others. (Thus, the discrete analogue of the exponential function is a solution of the recursion formula $f_{n+1} = af_n$, where a is a parameter and n a natural number.) A law statement containing a time variable helps one predict the time at which the thing in

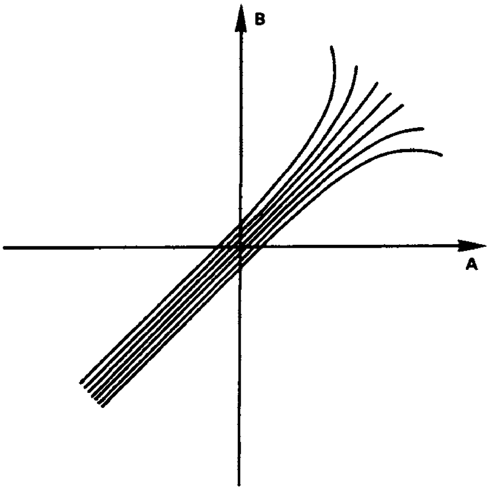

Fig. 9.13. A whole bundle of trajectories (e.g. life histories) in state space is described by a single law. Equivalently: a law is a bundle of possible histories.

question reaches a certain state. Likewise a law statement containing spatial coordinates helps us infer what happens at a given place from a knowledge of what is or was happening at another (e.g. on a surface surrounding the given place).

It is instructive to compare law statements with empirical generalizations, the former being the rationalist, the latter the empiricist paragon of scientific construct. Firstly, the empirical generalizations of the quantitative type, obtainable by interpolation techniques, are usually polynomials, which are stray not systemic functions. Not so the law statements, which contain systemic functions. Secondly, such polynomials contain adjustable parameters (one more than the degree of the polynomial). On the other hand the law statements, particularly of the mechanismic type, have a minimum of adjustable parameters. (The basic equations of electromagnetism and mechanics, whether classical or quantal, have no adjustable parameters at all: all the constants they contain are universal.) Thirdly, unlike the adjustable parameters in the empirical generalizations, the constants in the basic law statements have some factual meaning or other: they are universal constants. Fourthly, most basic law statements are mathematically more complicated than polynomials; even simple laws such as those of the oscillation period of a simple pendulum, and Snell's law of refraction, go far beyond polynomials.

Because of all these differences between law statements and empirical generalizations, the empiricist epistemology, which favors the latter and mistrusts or even rejects the former, does not fit the facts of scientific practice. Nor does critical rationalism, for which all hypotheses are groundless, none being better than any others except that some resist better the attempts at refuting them (Popper, 1959, 1963, 1974). As we saw before, a law statement is not just any hypothesis: it is a well-confirmed systemic hypothesis, hence one supported not only by data of a certain kind but also by all the data that support all the other hypotheses in the theory. Thus the laws of the hydrogen atom and the hydrogen molecule, of radiative decay and radioactive decay, of semiconductors and superconductors, derive from the basic laws of the quantum theory in conjunction with special assumptions; so, every time one of them is confirmed or refuted, its companions are confirmed or refuted.

Law statements can be classed in many ways: according to their logical form, mathematical properties, the kind of thing they refer to, their deductive power, generality, etc. (See Bunge (1963) for some such classings.) Here we shall mention only two distinctions, those between basic and derived, and between general and special. A *basic* law statement is one that occurs as a postulate or axiom in a general theory. Any logical consequence of basic law statements and definitions will be called a *derived* law statement. For example, the laws of conservation (of energy, linear momentum, etc.) follow from the equations of motion or field equations, which in turn follow from variational principles.

Our second partition of the set of law statements is into general and special. Since these terms are relative we must qualify them. We shall say that a law statement is *universal* in the collection F of factual items if it refers to every member of F—whether it holds for every one of them being another matter. The statement is *particular* in F if it refers to every member of a proper subset of F. The utmost general law statements are those concerning things of all kinds, from elementary particles to societies: they are the *universal* laws of ontology, such as "Every thing changes", "Nothing comes out of nothing", and "Every event is lawful". Then come the *generic* laws, i.e. those referring to all things of a given genus, e.g. bodies, electromagnetic fields, quantons, cells, societies, etc. Finally come the *specific* laws, i.e. those concerning all the members of a given species of thing, such as the so-called constitutive relations of continuum mechanics and electrodynamics, or all vertebrates, or all capitalist societies. Such specific law statements occur in all models or specific theories. Clearly, the reference class of a specific law is included in that of the generic laws, which in turn are included in the reference class of the universal laws. And even the most specific of all laws, such as those concerning the motions of individual planets and their satellites, are general in some respect, e.g. they hold for all times. In other words, scientific laws, just like the conventions of social behavior, are not concerned with minutiae: *De minimis lex non curat*.

Our last type of pattern is the rule. Rules are precepts or recipes for doing something. Unlike law statements, rules do not describe, explain or forecast: they prescribe. (The difference between rules and factual laws can be elucidated with the help of the state space formalism used in Vols. 3 and 4. A *law* of things of kind K is a mapping from the state space S_K of the K's into itself, i.e. $L_K : S_K \rightarrow S_K$. Thus, if s is a state of a thing of kind K, i.e. s is in S_K, then "$L_K(s) = t$", where $t \in S_K$ represents the lawful passing of the thing from state s to state t. On the other hand a *rule* may be construed as a mapping from the set of all possible states of the system of interest to a set of possible actions of the agents dealing with it. More precisely, a rule prescribing the behavior of animals of kind M with respect to things of kind K is a mapping of the state space S_K into a collection A_M of actions in the behavioral repertoire of the individuals of kind M. I.e., $R_{KM} : S_K \rightarrow A_M$. Thus if s is in S_K, then "$R_{KM}(s) = a$", where $a \in A_M$ is the action prescribed by rule R_{KM} for individuals of kind M facing a system of kind K in state s. The distinction between rule and law disappears only when $M = K$ and $A_M = S_K$, i.e. when agents and patients are the same, which is the case of the rules of social action. We shall return to this important point in Vol. 6.)

An *instruction* can be construed as a set or a sequence of rules for handling problems of some kind. If the problem is conceptual, the instruction directs thinking; if practical, it controls doing. An *algorithm* is a special kind of instruction, namely a sequence of rules for performing effective operations on symbols, and sure to halt at the result that is being sought. For example, an instruction for extracting square roots, or for computing the values of some function, is an algorithm; a correct computer program too can be regarded as an algorithm. Algorithms are supposed to be consistent with laws, but they are not laws themselves; sometimes they are just clever law-abiding tricks. In particular, as usually understood the laws of mathematics are about concepts, whereas algorithms are rules for manipulating symbols designating concepts. Besides, one and the same set of laws is consistent with a variety of algorithms, some more efficient than others. Thirdly, whereas all the mathematical laws are parts of theories, algorithms can be *ad hoc* and in any case they do not constitute hypothetico-deductive systems. So much for the algorithmic view of mathematics.

Animals and machines of certain kinds can be programmed or taught to follow instructions of certain types. Thus a Turing machine (an ideal computer) is characterized by its transition (or next state) function, which can be interpreted as embodying instructions of a certain kind—e.g. "When receiving input 1 while in state s, print 0 and jump to state t". A difference between an animal capable of learning and a Turing machine is that the latter has a fixed transition function built into it, whereas the animal can build and rebuild by itself a whole set of transition functions. (More on the difference between brain and machines in Vol. 4, Ch. 5.)

Whereas some rules are arbitrary, others are justifiable. The former are conventions, such as the rule that judges should wear black robes, and women discriminated against. A rule can be justified in either of two ways: practically (by success) or theoretically (by its compatibility with some theory). Thus until recently the medical rule "If you have a headache take an aspirin" was justified only practically. The theoretical justification of a rule consists in showing, with the help of some theory, *why* it is efficient. We call such rules *grounded.* And if the grounding theory is (sufficiently) true, the corresponding rules will be said to be *well grounded*; they may also be called *nomopragmatic* (instead of nomological) statements.

Take for example the so-called phase rule of thermodynamics: $C+2=P+F$, where C is the number of components, P the number of phases, and F the number of degrees of freedom of a system in equilibrium. Notwithstanding its name it is a law, for it belongs to a theory and concerns physical or chemical systems, not our actions on them. However, like many another law, the phase "rule" can be used to obtain certain desired effects. Thus, by increasing (decreasing) C we may cause an increase (decrease) in P. In other words, this law statement is the ground for a number of rules proper. All the rules employed in science and technology are supposed to be well grounded, for an empirical rule may be sheer superstition or, if effective, it may have unknown undesirable side effects. On the other hand the rules used or recommended by occultists, quacks, pseudoscientists, and unscientific ideologists are not well grounded.

The rule for obtaining a nomopragmatic statement from a nomological one is simple: Substitute a pragmatic expression for at least one of the expressions occurring in the law formula. Table 9.1 exhibits a few examples.

The relation between well grounded rules and the corresponding laws is

TABLE 9.1
Obtaining well grounded rules from law statements.

Law Schema	*Rule Schema*
1. When A rises B falls.	1. To decrease B, increase A.
2. If A happens B occurs.	2. When A is done B is found to happen.
3. For every x and some y, Fxy.	3. For any given x, some y may be found such that Fxy.
4. The rate of change of F equals G.	4. To vary the rate of change of F regulate G.
5. Every system has assembled from its components under suitable circumstances.	5. To manufacture a system bring its components together under suitable circumstances.

as follows. Consider an elementary rule schema of the form "To attain G use M", or *G per M* for short, where G is a goal and M a means. We stipulate that this rule is *well grounded* if, and only if, there is a law according to which M brings about G. In other words, the rule is well grounded only in case there is a reasonably well-confirmed theory containing a statement of the form "If M then G", where "M" and "G" are interpreted, in the theory, as properties, states, or events.

Note that the very same law statement that provides a basis for *G per M* supports also the dual rule *Non-G per non-M*, i.e. "To prevent G from being the case abstain from using M". (The contraposition of the law statement is not the ground of the dual rule. And in the latter the expressions of the form 'not-X' do not mean "anti-X" but merely the absence of X.) For example, "The output of an economic system is an increasing function of both capital and labor" provides the ground for two rules: "To increase output increase capital or labor", and "To decrease output decrease capital or labor". This practical ambivalence of law statements cannot be accounted for by pragmatism, which mistakes laws for prescriptions.

To say that a rule is *based* or *grounded* on a law statement is not to say that it follows from the latter—if only because every law statement supports a pair of rules. This point is of interest not only to the philosophy of technology but also to all the normative disciplines. In particular, to demand that the ethical and legal norms be well grounded—e.g. on psychology and sociology—does not amount to requiring that they be deducible from them. In other words, even if we wish the normative disciplines to be based on science we cannot reduce them to the latter. (This point will be discussed in detail in Vol. 7.)

Laws and rules may combine in yet another way, namely as rules helping or blocking the formulation of hypotheses expected to attain the rank of law. One such blocking rule is the commandment that scientific formulas ought to involve only functions representing observable properties. (Unfortunately for this rule all the basic concepts of the fundamental physical theories, in particular those of field intensity, Lagrangian, and state function, represent unobservables.) Another such rule, but this time a fertile one, is the correspondence principle: "Every new theory should contain, in some limit or other, the true, or approximately true, formulas of its predecessors". A third is the general covariance principle: "Every basic law ought to be frame-independent, i.e. to remain invariant under changes in frame of reference". This rule instructs us to get rid of constants specifying particular (e.g. egocentric) facts, and it has been a powerful stimulus to the construction of coordinate-free geometries. A fourth is the rule of equipresence, widely used in contemporary thermomechanics: "A magnitude present as an independent variable in one constitutive relation should be so present in all". This rule suggests including in every proposed constitutive relation all the variables occurring in other formulas of the same area.

Neither of the above principles represents a law of nature: all of them are heuristic rules concerning scientific hypotheses and theories. We call them *metanomological* statements. Clearly, they are rules or norms, hence efficient, inefficient, or counterproductive but not true or false. They are rules to be justified exclusively by their success in suggesting or eliminating hypotheses aiming at capturing objective patterns: they cannot be put to the test in the laboratory or in the field. On the other hand the statement that the basic equations of classical mechanics remain invariant under a transformation of coordinates mirroring an exchange of inertial (Galilean) frames of reference, is a metanomological statement that can be proved with pencil and paper. The same holds for the statement of the Lorentz invariance of the Maxwell equations, and of the charge-parity-time reversal invariance of all the basic local field theories. These metatheoretical statements are true, and their truth can be checked by purely conceptual operations, so they do not represent any real patterns. So much so that one can build any number of theories abiding by such principles and having nothing to do with reality. (For more on metanomological statements see Bunge (1963, 1967a).)

This concludes our treatment of laws and rules, subjects that, despite their centrality, are neglected by most philosophers—or, worse, they are mixed up with extraneous topics such as induction, counterfactuals, and possible worlds.

4. CONCLUDING REMARKS

Most of us go through life without ever encountering well-constructed classifications or hypothetico-deductive systems. We get by with vague classifications that are neither exclusive nor exhaustive, and with stray conjectures or tangled bodies of propositions that we dignify with the label 'theory'. In Antiquity only a handful of thinkers, such as Aristotle, Euclid and Archimedes, proposed reasonable classifications or well-built theories. In the Middle Ages only a few theologians, in the first place Thomas Aquinas, constructed hypothetico-deductive theories—albeit speculative ones. And in the Modern period there was no general theory before Newton's, and no general and correct classification before Linnaeus'. But from then on classifications and theories flourished and multiplied. In particular, theory has become so central to science and technology, that any discipline that lacks theories is properly regarded as nonscientific or, at best, protoscientific.

However, the careful and systematic analysis of classifications and theories did not begin until the 19th century, in the first place by Whewell (1847). Before him philosophers had no adequate conception of theories. Thus Bacon cared for none and explicitly rejected the few scientific theories of his time, and the British empiricists ignored factual theories altogether. Descartes and Leibniz thought scientific theories were a priori mathematical structures, and never thought it necessary to subject them to experimental tests. Kant did conceive of scientific theory as a synthesis of reason and experience—but the wrong kind of synthesis. Indeed he thought theories can account for appearance not reality, and he failed to understand the scientific theories of his time for want of mathematical knowledge.

We are better placed than our ancestors to analyze the logical structure of classifications and theories, because in the meantime logicians and mathematicians have forged the necessary tools of analysis, such as the predicate calculus, the theories of sets, lattices, filters, and ideals, model theory, and the calculus of theories. (See Tarski, 1956; Rasiowa and Sikorski, 1963; Bell and Slomson, 1969.) Yet, all this concerns structure not content. Accordingly only logicians and mathematicians have attained an adequate (though surely not final) understanding of their own systematizations. Many scientists, technologists and philosophers are often still confused or wrong about the nature of scientific and technological systematizations. This is partly explainable by the intrinsic difficulty of the subject: not only the formal structure or formalism but also the content is to be accounted for. (Hilbert said that he found physics much more difficult than mathematics.) But there is also the weight of tradition: mathematics has always been helped by rationalism and never been seriously hampered by empiricism. On the other hand factual science, technology and philosophy are still being hindered by empiricism.

The misunderstanding and even mistrust of theory among many philosophers is apparent in the half-century old debate on the status of theoretical concepts. Many are still worried by the fact that theories happen to contain theoretical concepts. The less sophisticated among them get away by decreeing that there is no problem: that every scientific theory concerns observations or measurements, not autonomously existing things (e.g. Simon and Groen, 1973). But of course this operationist reform (or rather destruction) does not work, because (*a*) measurement instruments are designed and operated with the help of theories, (*b*) we often find it necessary to correct measurement results in the light of theories, and (*c*) the basic concepts of the most advanced theories happen not to represent observable things or properties. (See e.g. Bunge, 1973a.)

Other philosophers recognize the existence of theoretical concepts but try to eliminate them by various ingenious techniques, of which the following are the best known. (*a*) Define the theoretical concepts in terms of observational ones, the way Mach tried to define "mass" as a ratio of accelerations. (*b*) Construct Ramsey sentences with the help of the empirical concepts of the theory (e.g. Carnap, 1966). (*c*) Pretend that the theory is composed of formulas that are either observational or theoretical, and apply Craig's theorem (Craig, 1956). None of these techniques work. Mach's because it presupposes the very law statements used to "define" the suspect concepts. (See Bunge, 1966). Ramsey's because the theoretical concepts must have been introduced, either as primitives or as defined concepts, before the postulates of the theory can be stated and conjoined to form a Ramsey sentence. And Craig's technique fails because it rests on the false assumption that it is possible to partition the set of formulas of a theory into observational and theoretical, while actually no factual theories contain strictly observational formulas. And all three

TABLE 9.2
Characterization of epistemologies with respect to their theses on the representability of scientific systematizations.

Epistemology	*Thesis*
Conventionalism	Do not represent: just colligate data.
Empiricism	Represent human experiences.
Pragmatism	Do not represent: are just tools for action.
Naive realism	Represent directly and faithfully.
Critical realism	Represent indirectly and, at best, approximately.

theory demolition techniques fail because they ignore that factual theories happen to be about concrete things existing whether we know it or not, and having properties that can be represented only by sophisticated concepts. (For further criticisms see Bunge (1967a, 1973a, 1973b), and Tuomela (1973).) This view, critical realism, contrasts with the alternative views as shown in Table 9.2.

Finally let us define the reference, extension, scope, and power of a factual theory, and let us evaluate theorizing in general. The *reference* (class) of a theory is of course the collection of its referents. These are not only the actual and investigated ones but all of the possible things of a kind—e.g. all the possible biopopulations in the case of the genetics of populations. (See Vol. 1, Ch. 2.) On the other hand the *extension* of a theory T may be defined as the collection of referents of T for which T has been confirmed reasonably well, i.e. for which T holds with good approximation. Note that the extension of a theory is a subset of its reference, and that it is a variable collection rather than a fixed set, for the incoming empirical information is likely to expand or shrink, in the course of time, the range of things that are adequately covered by the theory.

The *scope* of a theory may be defined as the set of events it allows or regards as lawful, i.e. the event space it assigns to its referents. (The event space of things of kind K is properly included in the cartesian product of the state space S_K by itself—i.e. it is the set of pairs of states compatible with the laws of things of kind K. See Vol. 3, Ch. 5.) The more general a theory, the greater its scope. As a theory is adjoined subsidiary hypotheses accounting for details of its referents, its scope shrinks: it tells us more and more about less and less. We need theories of all scopes except the two extremes of complete restriction ("Nothing ever happens") and total permissiveness ("Anything goes"). The former extreme must be avoided because it leaves nothing to be investigated, the latter because it has no explanatory power and consecrates magic.

The *power* of a theory is measurable by the number of bits of knowledge it systematizes—in particular the number of precursor hypotheses it puts together—and the number of new items it introduces. Of all available scientific theories the quantum theory and the synthetic theory of evolution are the most powerful. But such power, though great, is not unlimited: no theory can embrace all the knowledge in a given field. The reason for this limitation is that a factual theory should contain no data. All we demand of theories is that they contain blanks that can be filled out with empirical data every time we apply them to solve particular problems. (Recall Section 2.2.)

As for the value of theories, different people value them differently. To theoretical scientists and rationalist philosophers, theory is at the very top, for it constitutes the best possible systematization, extrapolation, and exactification of a body of knowledge. To descriptive scientists, empiricists, philosophers, and laymen, theory is a matter of either indifference or embarrassment for overreaching experience, and so it is at the very bottom of their scale of values. And to workers in experimental science and technology, theory is right in the middle, for they are guided by theories and they know their discoveries or inventions motivate the building and correction of theories. The realist epistemologist values equally theory and experiment: to him it is a truism that theory without empirical support is sheer speculation, whereas empirical operation without theoretical backing is a waste of time.

This concludes the first part of our study of epistemology and methodology. The second part, titled *Understanding the World*, examines the ways we account for facts and check and evaluate our hypotheses, theories and proposals. It also discusses the varieties of human knowledge and of changes of it. Finally, it formulates and defends the general view resulting from our study, namely scientific realism.

APPENDIX 1

THE POWER OF MATHEMATICS IN THEORY CONSTRUCTION: A SIMPLE MODEL OF EVOLUTION

To illustrate the power of mathematics in the construction of theories consider the following simple-minded model of evolution representing the two main evolutionary "forces", namely random mutation and selection by the environment. (This model is quite different from the one in Vol. 4, Ch. 3, Section 3.4.) The evolving units may be populations of molecules, stars, organisms, or social systems: the theory does not specify the precise mutation or selection mechanisms. We assume that the components of such a population are subject to mutation, whether genic or of some other type, spontaneous or induced by environmental agents, but in any case "blind" or random, in the sense that the probability of a mutation is independent of its survival value for the component. We also suppose, for the sake of simplicity, that there is a single kind of mutation and that some of the mutants happen to be viable, so that in the course of time a second population emerges, namely that of mutants. Call the latter M and that of normals N. Suppose also that the mutations are irreversible and that the mutants themselves are stable, i.e. immune to any further mutations, so that they contribute neither to the normal population nor to any third group. Besides, assume that all the normals have the same probability p of originating mutating offspring, and that on the average each normal has a descendants, where $a > 1$. Finally, suppose that all of the viable individuals endure, regardless of their age, for a large number g of generations. Note that our model contains no less than six simplifying assumptions, most of which are at best only approximately true.

Our problems are (*a*) to trace the speciation process, i.e. the growth of the M population, and (*b*) to estimate the mutation parameter p from a count of the fraction of mutants in the total population after g generations. We start by noting that, since the probability of a mutation from one generation to the next is p, the probability that no such change occurs during the same period is $1-p$, and the probability that a normal individual will originate normal offspring at generation n will be

$$v_n = (1-p)^n.$$

Consequently the probability that an organism taken at random from the total population at generation n be a mutant, is the complement of v_n to unity, i.e.

$$\mu_m = 1 - (1 - p)^n.$$

Recall now that every normal individual produces, on the average, a descendants. Hence the average number of normals at generation n is

$$N_n = a^n v_n = a^n(1 - p)^n.$$

Therefore the total average of normals for all g generations is

$$N = \sum_0^g N_n = \sum_0^g a^n(1 - p)^n = \frac{(a(1 - p))^{g+1} - 1}{a(1 - p) - 1}.$$

To compute the corresponding number M of mutants produced at generation g assume that on the average every mutant produces b offspring, where b is in general different from a—in fact greater than a if the mutants are fitter than the normals. Hence the average number of mutants at generation n is

$$M_n = b^n \mu_n = b^n(1 - (1 - p)^n).$$

Consequently the average number of mutants at generation g is

$$M = \sum_0^g M_n = \sum_0^g b^n(1 - (1 - p)^n) = \sum_0^g b^n - \sum_0^g (b(1 - p))^n$$
$$= \frac{b^{g+1} - 1}{b - 1} - \frac{(b(1 - p))^{g+1} - 1}{b(1 - p) - 1}.$$

What can be observed directly are the totals N and M. From them we can estimate the mutation parameter p as follows. To simplify the calculations make the unrealistic pretense that the mutants are just as fit as the normals, i.e. set $a = b$, and use the previous results to form the fraction of normals:

$$\frac{N}{N + M} = \frac{\dfrac{(a(1 - p))^{g+1} - 1}{a(1 - p) - 1}}{\dfrac{a^{g+1} - 1}{a - 1}} \cong (1 - p)^{g+1},$$

since, for small p, $a(1 - p) \cong a$. Finally we obtain

$$p \cong 1 - \left(\frac{N}{N + M}\right)^{1/(g+1)}.$$

For example, for $p = 0.001$ and $g = 99$, the total fraction of mutants proves to be 0.1, an appreciable number. If the mutation probability is tenfold, the mutant population attains over one third of the total. But even a small mutation probability can be compensated for by a large fitness or fertility value. In other words, a favorable environment can make up for a small chance of an individual change.

Note the following points. First, the entire model involves only a couple of theorems in the elementary calculus of probability and a handful of algebraic manipulations. Second, every assumption is translated into mathematical terms, and every mathematical result is translated back into scientific terms, i.e. is assigned a factual interpretation. Third, the last two formulas, which relate the unobserved probability p to the observable frequency $N/(N+M)$, is characteristic of this theory. Different stochastic theories contain different relations between the two quantities—or none. (Therefore, it is hopeless to try and define probability as long term frequency, the way empiricists have tried. In general, theoretical concepts cannot be defined in terms of empirical ones or conversely. But they can be related.)

THE PROSE IDENTIFYING THE VARIABLES

Take the hypothesis that frustration builds up latent aggression (i.e. aggressiveness). This hypothesis may be taken as the precursor of a theory composed of mathematical formulas and semantic formulas. Let us proceed to build the simplest possible such theory.

We start by defining frustration as the percentage of unfulfilled desired acts, and postulate that latent aggression (or aggressive disposition) is proportional to manifest aggression. That is, we set

$$F=(D-P)/D \qquad \textit{Definition} \quad (1)$$

and

$$A=aN, \qquad \textit{Hypothesis} \quad (2)$$

where "D" and "P" stand for desired and performed acts of some kind respectively, while "N" stands for the total number of aggressions and "a" their intensity, assumed to be constant for the sake of simplicity.

We can now state the original (precursor) hypothesis in a definite fashion:

$$A=bF, \qquad \textit{Hypothesis} \quad (3)$$

where b is a positive real number. Obviously, this assumption of mere proportionality between aggressiveness and frustration is too simple to be true. But our purpose is semantic insight not factual truth.

Substituting (1) and (3) into (2) we obtain a testable consequence:

$$N=b(D-P)/aD. \qquad \textit{Theorem} \quad (4)$$

Finally we may collect the above formulas, restate them more carefully, and surround them with the requisite mathematical and semantical formulas. The result is this:

Primitive concepts
Set S of subjects
Number D of desired acts of a given kind per unit time
Number P of desired and performed acts of a given kind per unit time
Number N of aggressive acts per unit time

Defined concept

Frustration $F = (D - P)/D$

Postulates

Mathematical 1 $D, P: S \to \mathbb{N}$.
Mathematical 2 $A, a: S \to \mathbb{R}^+$
Mathematical 3 $b \in \mathbb{R}^+$
Factual 1 For every x in S, $F(x) = a(x)N(x)$.
Factual 2 For every x in S, $A(x) = bF(x)$.
Semantic 1 "$A(x)$" represents the aggressiveness of subject x.
Semantic 2 "$F(x)$" represents the frustration felt by subject x.
Semantic 3 "$a(x)$" represents the intensity of the aggressive acts committed by subject x.

Theorem

For every x in S, $N(x) = b[D(x) - P(x)]/a(x)D(x)$.

The same mathematical and factual axioms may occur in totally different contexts accompanied by corresponding different semantic axioms. And if the former are changed then the latter too may have to be modified. For example, instead of construing frustration and aggressiveness as numerical variables we may work with the sets of aggressive acts and desired acts, whether performed or frustrated. And we may then try a probabilistic version of the precursor hypothesis, such as, e.g.,

For any subject x, every a in A, every f in F, and every p in P,

$$Pr(a|f) = a(x)[1 - Pr(a|p)], \quad \text{with } a(x) > 1.$$

The semantic assumptions are now

$S1$ "$Pr(a|f)$" represents the propensity (tendency) of a subject to commit an aggressive act when he feels a frustrated desire f.
$S2$ "$Pr(a|p)$" represents the propensity (tendency) of a subject to commit an aggressive act when he has fulfilled desire p.
$S3$ "$a(x)$" represents the natural aggressiveness of the subject x.

The point is that every formalizations calls for its own set of semantic formulas, without which we would not know what it represents.

GENERAL PREFACE TO THE *TREATISE*

This volume is part of a comprehensive *Treatise on Basic Philosophy*. The treatise encompasses what the author takes to be the nucleus of contemporary philosophy, namely semantics (theories of meaning and truth), epistemology (theories of knowledge), metaphysics (general theories of the world), and ethics (theories of value and of right action).

Social philosophy, political philosophy, legal philosophy, the philosophy of education, aesthetics, the philosophy of religion and other branches of philosophy have been excluded from the above *quadrivium* either because they have been absorbed by the sciences of man or because they may be regarded as applications of both fundamental philosophy and logic. Nor has logic been included in the *Treatise* although it is as much a part of philosophy as it is of mathematics. The reason for this exclusion is that logic has become a subject so technical that only mathematicians can hope to make original contributions to it. We have just borrowed whatever logic we use.

The philosophy expounded in the *Treatise* is systematic and, to some extent, also exact and scientific. That is, the philosophical theories formulated in these volumes are (*a*) formulated in certain exact (mathematical) languages and (*b*) hoped to be consistent with contemporary science.

Now a word of apology for attempting to build a system of basic philosophy. As we are supposed to live in the age of analysis, it may well be wondered whether there is any room left, except in the cemeteries of ideas, for philosophical syntheses. The author's opinion is that analysis, though necessary, is insufficient—except of course for destruction. The ultimate goal of theoretical research, be it in philosophy, science, or mathematics, is the construction of systems, i.e. theories. Moreover these theories should be articulated into systems rather than being disjoint, let alone mutually at odds.

Once we have got a system we may proceed to taking it apart. First the tree, then the sawdust. And having attained the sawdust stage we should move on to the next, namely the building of further systems. And this for three reasons: because the world itself is systemic, because no idea can

become fully clear unless it is embedded in some system or other, and because sawdust philosophy is rather boring.

The author dedicates this work to his philosophy teacher

Kanenas T. Pota

in gratitude for his advice: "Do your own thing. Your reward will be doing it, your punishment having done it".

PREFACE TO *EPISTEMOLOGY II*

This is the sequel to *Epistemology I: Exploring the World.* In that work we studied cognition as a brain process, and communication as a social transaction. In particular, we studied perception and conception, the formation of propositions and proposals, exploration and systematization, discovery and invention. We regarded knowledge as an outcome of processes occurring in animals that learn by themselves and from one another. We took concepts and propositions, problems and proposals, to be equivalence classes of brain processes rather than ideal objects detached from brains and from society. However, we also stressed the need for studying such abstractions as well as the corresponding real processes.

In other words, we admitted that cognition ought to be studied both concretely (as a biopsychosocial process) and abstractly (with disregard for personal and social idiosyncrasies). We hoped in this way to favor the merger of the various hitherto separate approaches to the study of knowledge and knowledge-directed action: the neurophysiological and the psychological, the sociological and the historical, the epistemological and the methodological ones. After all, these various approaches have a single aim, namely to improve our understanding of the ways we get to know reality, and the ways knowledge can be utilized to alter reality.

In this volume we will study the ways theories and proposals (e.g. technological designs) are put to the test and used to understand or alter reality. We will stress the difference between belief and inquiry. We will study the kinds of knowledge and the ways human knowledge grows, declines, or alters course. We will distinguish basic science from applied science, and both from technology and ideology, and we will seek to demarcate genuine knowledge from bogus. We will analyze the two mechanisms for enhancing the cross-fertilization and the unity of the various branches of knowledge: reduction and integration. We will stipulate the conceptual and empirical conditions a proposition has to fulfill in order to be valued as (sufficiently) true, and a proposal to be regarded as (suitably) efficient. (We shall do so in the light of real cases drawn from contemporary research rather than in obedience to a priori philosophical principles.) We will analyze a number of important yet vague notions, such as those of truth and efficiency, background and framework, paradigm and revolution. And we will explore the possible limits to our exploration of the world, as well as the limitations of the classical philosophies of knowledge.

The upshot of our study is a descriptive and normative epistemology that cannot be compressed into a couple of slogans, although it combines some features of rationalism with others of empiricism. This synthesis may be called *scientific realism* because the criterion for adopting or rejecting any given thesis is its compatibility or incompatibility with the practice of research in contemporary science (basic or applied), technology, or the humanities. We find no use for a theory of knowledge, however exact or ingenious it may be, that is divorced from knowledge.

SPECIAL SYMBOLS

$\neg p$	*not-p*
$p \& q$	*p and q* (*conjunction*)
$p \vee q$	*p or q* (*disjunction*)
$p \Rightarrow q$	If *p*, then *q* (*implication*)
$p \Leftrightarrow q$	If *p*, then *q*, and conversely (*iff*)
$A \vdash B$	Premises *A entail* conclusions *B*
$=_{df}$	Identical by *definition*
$\{x \mid Fx\}$	The *set* of objects possessing property *F*
$\emptyset$	The *empty set*
$a \in A$	Individual *a belongs to* set *A*
$A \subseteq B$	Set *A* is *included* in set *B*
$A \cup B$	The sets of objects in *A or* in *B*
$A \cap B$	The set of objects in *A and* in *B*
$A - B$	The set of objects in *A* but *not in B*
$A \Delta B$	The set of objects in *A or* in *B* but *not in both*
$\langle a, b \rangle$	The *order pair* of *a* and *b*
$A \times B$	The *cartesian product of A* and *B*, i.e. the set of ordered pairs $\langle a, b \rangle$, where *a* is in *A* and *b* in *B*
2^A	The *power set* family of all subsets) of set *A*
$\lvert A \rvert$	The *cardinality* (numerosity) of set *A*
$\mathbb{N}$	The set of *natural numbers* (0, 1, 2, . . .)
$\mathbb{R}$	The *real line*
$\mathbb{R}^+$	The set of *non-negative real numbers*
$f: A \rightarrow B$	The *function f* maps set *A* into set *B*
$f(x)$	The *value* of function *f* at *x*
$F = \langle F_1, F_2, \ldots, F_n, \ldots \rangle$	A state function for some system
R & D	Research and development
S & T	Science and technology

PART IV

UNDERSTANDING AND CHECKING

CHAPTER 10

UNDERSTANDING

We do a number of things, from eating to learning to write, without understanding what we are doing. Automatic machines and computers, too, perform their task without understanding. But their designers, repairmen and users are supposed to understand, at least to some extent, what they do. All intellectual and technical operations require some understanding unless they follow routines; and even when they do so the control of the results requires some understanding of the nature, goal and value of the operations.

Understanding is not an all-or-none operation: it comes in several kinds and degrees. Even after studying a subject for decades we may feel that we can still make progress at understanding it: we learn to see it in different ways, to relate it to different themes, or to use it in different ways. Until a time may come when, having understood the subject fairly well, we realize that it is error ridden or has become obsolete.

Consider the following imaginary dialogue. "What is new?—President *X* died.—How, when, where?—He was murdered yesterday at *Y*.—Why?—The inquiry is still under way." The point of this dialogue is to note three different and successive stages in any thorough inquiry into factual matters, namely finding the *what*, the *how*, and the *why*—or information, description, and explanation respectively.

A set of raw data tells us that something is or is not the case. A description tells us how the fact has come about. An explanation is one more step in the process of inquiry. It involves conjecturing mechanisms of some kind—causal, stochastic, teleological, or a combination of these—underlying the facts being described. In the above example any of the following may turn out to be part of the correct explanation. The assassin was crazy; he wanted to attain notoriety; he was an enemy agent; he had a grudge to avenge; he regarded the victim as public vermin; he wanted to replace the victim; he wanted to trigger an uprising. Any of these statements, though schematic, goes beyond the mere description of the fact: it is a hypothesis. By adopting any of it we may expedite or block the research and thus favor or hinder the process of refining the original description.

We may understand or fail to understand the what, the how, and the why of a fact, and we may do so in different manners and to different degrees. But, in all cases of genuine knowledge, knowing that something is (or could be) the case precedes knowing how, which in turn precedes knowing why. (This does not hold for ideological explanation, which dispenses with inquiry altogether.) It follows that explanatory knowledge is superior to descriptive knowledge, which is in turn superior to mere information. That is, knowing why implies knowing how, which in turn implies knowing that.

To admit the above involves adopting an epistemology at variance with empiricism, which counsels description and discourages explanation. By the same token it involves sharing the belief, widespread among scientists, technologists, and humanists, that explanation is a goal of research as distinct from mere inquiry, which usually stops as the how. But admitting all this is of little value unless we know what is explanation. We shall therefore undertake to examine explanation.

1. UNDERSTANDING AND EXPLAINING

1.1. *Modes of Understanding*

We can understand, or misunderstand, objects of various categories: facts, signs, and constructs. Thus we can understand what happens around us, we can understand a sentence, and we can understand a hypothesis. In principle anything can be the object of understanding—even non-facts such as travel at superluminal speed and the adventures of disembodied spirits. Nor are the understandings of objects of different types unrelated. Thus to understand a fact one needs to know other facts and some hypotheses. And to understand a theory one needs to understand some of the sentences in which its formulas are expressed.

One may understand in different ways and degrees. One may understand with the help of words or diagrams, examples or analogies, empathy or hypotheses. To be sure, these various modes of understanding are inequivalent, but the point is that they constitute understanding even if not all of them amount to genuine explanation. Thus we may understand the apparently odd behavior of someone else if we make an effort to put ourselves in his shoes: this is an act of empathic understanding or *Verstehen*, made possible by the basic similarity of all human brains. We understand *A*'s dislike for *B*'s philosophy when informed that B stole A's bride (or hypothesis or experiment). Dalton understood atomic combinations in terms of tiny hooks. Faraday understood electromagnetic induction in terms of elastic tubes. Darwin understood natural selection by likening it to economic competition.

Metaphorical explanation is not limited to lay discourse: one often finds it in the beginning stages of scientific and technological developments, even in sophisticated fields such as many body physics. Thus consider a network of atoms or molecules. One of them absorbs a photon and so gets excited, i.e. jumps to a higher energy state. This excitation, an event, is reified into an "exciton", which is treated *as if* it were a particle. Indeed, when the excitation propagates to a neighboring atom or molecule, the exciton is said to pass on from one atom (or molecule) to the next. Since this hopping goes on at random, it is treated *as if* the exciton "were enjoying a random walk through the lattice", as one author puts it. (I.e., the metaphorical exciton is likened to a drunkard—a metaphor of a metaphor—so that the theory of random walk can be used.) Eventually the exciton ceases to wander: this event is treated *as if* the exciton had fallen into a trap ("trapping center") where the exciton triggers a chemical reaction. The entire metaphor has as much heuristic value as Faraday's analogy between the electromagnetic field and the elastic solid. And in both cases this heuristic scaffolding is eventually dismantled: only the equations remain, which are interpreted in a different (literal) way. A new, superior, mode of understanding is attained.

In any of its modes understanding involves systematizing—or, as Piaget would have said, assimilating. Either we fit the given item into our pre-existing cognitive or epistemic network, or we transform (e.g. expand) the latter to accommodate the new item. See Figure 10.1. Needless to say, this is a metaphorical explanation of the phenomenon of understanding. Like some other metaphorical explanations, it may prove to be of heuristic value: it may suggest a precise formulation in terms of changes in the state space of a psychon or plastic neural system.

Every student is familiar with the phenomenon of the growth of understanding, which at times is gradual and at other times sudden, and at all times is a matter of degree or level. The first reading of a paper may give him a dim understanding, a second a deeper understanding, and a third, perhaps apparently unrelated experience, may show how everything falls into place. We understand a thing or a process if we are given a description of it; we understand it even better if the description follows from some mechanismic model.

What holds for individual learning holds, *mutatis mutandis*, for the social

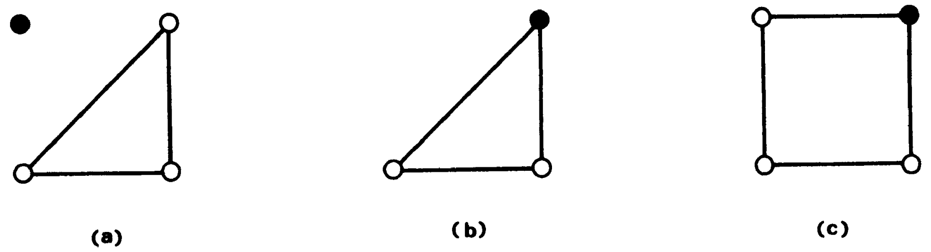

Fig. 10.1. Understanding as systematization. (*a*) Before understanding item symbolized by black dot. (*b*) Item is understood by fitting into pre-existing epistemic network. (*c*) Item is understood by transforming epistemic network.

process of growth and diffusion of knowledge. Along the history of any epistemic field metaphors are replaced by literal descriptions, which are systematized into black boxes, which are superseded by mechanismic theories, which in turn make it possible to refine descriptions. A few historical examples will help us understand this point.

Take for instance solidity: we understand it on being told that the inter-particle distances in a solid are constant. If we now ask why those distances are constant, we demand a theory involving inter-particle forces, i.e. a mechanismic or dynamical theory. Take disintegration next: an exponential decay curve, or the corresponding equation, answers the how-question but does not explain why there is disintegration rather than stability. An explanation requires a theory involving the hypothesis that special forces are involved. Or take high energy processes such as the high speed collision of protons with neutrons and the resulting ménagerie of particles. Until recently physicists were satisfied with data fitting and with black box models capable of absorbing and occasionally predicting large amounts of data but incapable of explaining them. The currently popular theories go far beyond that phenomenology and hypothesize that many a so called "observed particle" is a system—e.g. one composed of quarks and antiquarks bound together by peculiar forces.

Nor is the above pattern of progress restricted to physics. Chemistry has long ceased to be a huge catalogue of reactions and compounds. We know now the composition and structure of millions of compounds, and are beginning to explain their very existence in terms of forces and collisions. Likewise biochemistry is advancing from description to explanation. At the time of Claude Bernard biochemistry was mainly concerned with establishing balance sheets, i.e. with relating what the organism consumes with what it excretes. For example, the amount of protein consumed was correlated with the amount of urea and creatinin in urine: the intermediate processes were unknown. Nowadays a number of metabolic pathways have been uncovered, and many biosynthesis processes, such as photosynthesis, have been analyzed. The same holds for the adjoining field of genetics. Classical genetics treated the organism as a black box and, accordingly, performed observations and experiments on the whole organism level—e.g. hybridization experiments. With the discovery and chemical identification of the gene, and particularly with the formulation and confirmation of the double helix hypothesis, the genome became a grey box. True, biochemistry and genetics are still primarily structural and kinetic, and only marginally dynamical. But it is likely that more and more dynamical (mechanismic) models, explaining the known structures and processes, will be proposed as theorists invade the field in increasing numbers. As Francis Crick, of double helix fame, once said, "One man's black box is another man's problem".

Biology is no exception to the general trend from description to explanation. True, much of biology is still descriptive and classificatory, and talk of information flow, and even of goal, often passes for explanation. Still, all biologists pay at least lip service to the synthetic theory of evolution, which is a mechanismic theory, and acknowledge that biological research cannot go far without physics and chemistry in the search for the mechanisms of processes. An increasing number of biologists are working on mathematical models of biological processes on the various biolevels, from the cellular to the ecosystemic. All biologists realize that, in order to know how a bird flies, it suffices to film it in flight; but that, if we wish to understand how it manages to fly, we must create and test models of the mechanics and physiology of bird flight. Likewise psychologists are beginning to learn that behavior, far from explaining, is the thing to be explained: that there are no kinematical explanations but only kinematical descriptions. In particular some of them are learning that only physiology and sociology can explain human behavior. At the same time historians are realizing that chronicling does not suffice: that we can understand historical processes with the help of disciplines other than history, in particular psychology, demography, sociology, economics, and politology. Moreover they have learned that consideration of these disciplines elicits the search for new data as well as the framing of descriptions that would otherwise not be forthcoming.

In sum, in all epistemic fields the tendency has been to advance from description to explanation, from black to grey to translucid boxes, from the ledger to the clockwork. This is no accident but an indication that, although we can understand in various ways, only a mechanismic (or translucid box) theory can give us a satisfactory understanding of things, for it alone can tell us what makes things tick. Not that the above mentioned trend is inevitable: like every other trend it might be reversed. As a matter of fact the current computer fad is already distorting that trend: the lust for computation and simulation dries up the passion for explanation. To be sure we need both computation and simulation, but neither is enough, for neither brings insight. (In particular, the numerical solutions to equations are unwieldly and hard if not impossible to interpret.)

1.2. *Subsuming and Explaining*

Let us analyze three epistemic operations that, though distinct, are often confused: description, subsumption, and explanation. From a logical viewpoint a *description* is an ordered set of factual statements. For example, "The car came at high speed, crashed against the fire hydrant, and stopped". (If the data came in reverse order, the description had to be conjectured.) Given that description we may understand some of the related facts, such as the final state of the driver, the car, and the fire hydrant—but this only because we use tacitly certain generalizations about the effects of impact. But the description does not explain why the driver crashed in the first place: was he drunk, was he sick, did the car have a mechanical defect, was the pavement slippery? Only further data and hypotheses can answer the why-questions.

A *subsumption* too is an ordered set of statements, but one such that the last statement follows from the preceding ones. For example, suppose we want to account for the fact that a given population of bacteria has increased eight-fold in the term of one hour. We investigate the matter, counting (or sampling) the population every so often, and come up with a table or a graph population *vs.* time. Suppose we find that the growth pattern is 1, 2, 4, 8, 16, 32, 64, etc., at 20 minute intervals. This accounts for the fact to be understood, since we recognize it as the 4th member of the sequence. In other words the fact has been *subsumed* under a general pattern, namely: The given population of bacteria doubles every 20 minutes. In other words, we have turned the fact to be explained into a particular case of a law statement.

The inference has been this:

For every x and every t, if x is a population of bacteria of species A in condition B, then the population of x at $(t + 20)$ min is twice the population of x at t. [In general, $N_t = N_0 2^t$, where N_0 is the initial population and t is the number of 20 min periods.]

b at $t = 0$ is a population of N_0 bacteria of species A in condition B.

b at $t = 60$ min is a population of $N_3 = 8N_0$ bacteria of species A in condition B.

Generalizing, the basic subsumption schema is this:

Pattern	*For all x, if Fx then Gx*
Circumstance	*Fb*
Given fact	*Gb*

↓*Deduction*

Sometimes the pattern occurring in a subsumption is merely a systematic or classificatory statement. For example, "Johnny does X because he is (in the class of children who are) 7 years old" is typical of Piagetian psychology. It accounts for a property of an individual in terms of its belonging to a certain kind. And "Helium has a very low reactivity because it is a noble element" accounts for a property shared by all the members of a species by including the latter in a certain genus. In both cases the inference patterns are strictly deductive:

Explanation of individual property in terms of belonging to a species

Premise 1: Definition of species S by the characteristic properties $A, B, \ldots, X, \ldots$ of its members.

Premise 2: b belongs to S.

Conclusion: b possesses property X.

Explanation of species property in terms of inclusion in a genus

Premise 1: Definition of genus G by the characteristic properties $M, N, \ldots, Y, \ldots$ of its members.

Premise 2: S is included in G

Conclusion: Every member of S possesses property Y.

We understand the given fact as a particular case of a general pattern. Still, we do not understand the pattern itself, and therefore the fact to be accounted for remains half understood. We are told how things are, not why they should be the way they are. From a logical point of view bacteria might grow in many different ways or in none. But microbiological research reveals that bacterial colonies happen to grow by division. In our example, every bacterium of species A divides at the end of 20 min; in turn, every daughter bacterium divides after 20 min, so that the original bacterium has been replaced by four, and so on. This then is the (main) growth mechanism in the case of populations of bacteria (and other unicellular organisms): cellular division. (To be sure it is a nonmechanical mechanism.) We have now attained an *explanation* proper, or mechanismic account.

The logical reconstruction of the explanation process is this. From the observation and timing of cell division we hypothesize (and check) the law of growth, namely $N_t = N_0 2^t$. (We can obtain this hypothesis by a rigorous application of the mathematical principle of complete induction. But of course this is no proof that bacteria do grow that way. Only experiment can tell whether the hypothesis is true. In fact we know that it fails for high population densities, i.e. where there is strong competition for resources.) The rest follows like in the case of subsumption.

The difference between subsumption and explanation is not logical: both are cases of deduction from regularities and circumstances, in particular law statements and data. The difference is another one. Subsumption answers only how-questions, explanation how-or-why-questions, such as 'How does this machine work?' and 'Why did this machine go out of order? Both answers or accounts are given in terms of patterns, such as trends, empirical generalizations, or law statements: the given fact to be accounted for is shown to be a particular case of such pattern. But whereas in the case of subsumption the pattern itself remains unaccounted for, in the case of explanation it is a mechanismic hypothesis or theory.

The basic logical pattern of subsumption was

(1) *For all x, if Fx then Gx, Fb* $\vdash$ *Gb.*

The corresponding pattern of explanation is this one:

(2) *For all x, if Fx then Mx, For all x, if Mx, then Gx, Fb* $\vdash$ *Gb,*

where 'M' symbolizes some mechanism such as cell division. (For example, the first premise could be "For every x, if x is a bacterium, then x reproduces by cell division", and the second "If x reproduces by cell division, then the offspring of x grows geometrically".) Now, the two general premises of (2) jointly entail the general premise of (1). Phenomenalists, conventionalists and simplicists would say that this shows that 'M' is dispensable or replaceable. A realist concludes instead that *explanation subsumes subsumption,* logically, epistemologically and ontologically. Logically because, given an explanation, we can detach the corresponding subsumption. Epistemologically because explanation presupposes more knowledge than subsumption. Ontologically because explanation goes deeper into the matter than subsumption, by pointing to some (conjectured or established) mechanism that may be hidden to the senses. Let us dwell for a moment on the epistemological and ontological aspects of explanation that we have just noted.

That explanation involves subsumption is suggested, though not proved, by the following examples. (*a*) Knowing that the mechanism of radio communication is electromagnetic field propagation, we know how it can be produced, how it proceeds, how long it takes—hence when the signal is to be expected—how it may be detected, amplified, etc. (*b*) Knowing that the mechanism of heredity is summarized in the vicissitudes of the parental DNA molecules, we know in principle how hereditary traits appear and fail to appear, and how they could be modified. (*c*) If we knew the neurophysiological mechanism of problem solving we would be able to solve a whole cluster of problems, such as: What particular neural systems work out the problem?, How does the problem solving process proceed, and When do the various stages in the process occur? In sum, knowing the most involves knowing the least. Hence descriptivism—the epistemology that extols description and decries explanation—hampers the advancement of knowledge.

The relations between explanation and ontology are as follows. Firstly, the quest for explanation is a quest for knowing deeper and deeper levels of reality. (For the concept of a level see Vol. 4, Ch. 1.) Secondly, the very choice of a type of explanation presupposes some ontology or other. Thus a theological world view suggests explaining natural and social facts ultimately in supernaturalistic terms, or even holding that they are unexplainable. A physicalist (or vulgar materialist) ontology suggests looking for explanations in physical terms even in the case of biological, psychological, and social facts. On the other hand, emergentist materialism (Bunge, 1981a) acknowledges the emergence of qualitative novelty and it encourages its explanation. (Holism denies that such explanation is possible, and reductionism denies emergence altogether.) Thirdly, to explain a fact is to show how it comes about, not to eliminate it. Thus to explain an illusion is to disclose its neurophysiological mechanism, not to show that it did not occur to begin with. (On the other hand Coren and Girgus (1978, p. 23) hold that "Ultimately, when we know exactly how the visual system works, visual illusions should no longer exist".) In sum explanation, unlike definition, does not eliminate. And inexplicability (or mysteriousness) does not define. For example, *pace* numerous philosophers, "emergence" is not definable as unexplained novelty, and "illusion" is not definable as unreality.

An explanation is an epistemic process involving three components: (*a*) an explainer or animal doing the explaining; (*b*) the object(s) of the explanation, i.e. that which is explained, and (*c*) the explanatory premises or *explanans*. All the explainers we know are humans: we do not know whether any other animals explain, and we will never know unless the question is seriously posed. (True, we often say that a hypothesis or a theory explains such and such facts. But this is by way of metaphor: we mean that a knowing subject explains facts with the help of a theory and data.) The objects of explanation are facts. And the explanatory premises are the hypotheses and data involved in the explanation.

What can be objects of explanation? A sybilline answer is: Anything problematic. But of course what is problematic depends on the general framework as well as on the state of knowledge. Thus a philosopher obsessed with nothingness finds it natural to ask why there is something rather than nothing, whereas a scientist takes the universe for granted and asks instead why things change the way they do, as well as why certain things seem not to change at all. Neither believers nor atheists ask why there is a deity: the former because they take it for granted, and the latter because they deny its existence. The evolutionary biologist asks why the known species have the properties they have, whereas the creationist has no such problem. The nonconformist asks why we should keep certain institutions which the conformist does not question. In sum, each world view encourages the search for certain explanations while discouraging others.

Aside from considerations about world views, the objects of explanation can be things, properties or states of things, or events (changes in things). A (concrete) *thing* is explained if a possible process is found or conjectured that ends up in the emergence of the thing—e.g. the formation of a molecule or of a social system. (Accordingly the stable elementary particles, such as the electrons, are not explainable except when they result from processes such as nuclear disintegration or high energy collision.) Likewise a *property* is explained in terms of some process of qualitative change—e.g. the emergence of the questioning ability during human development. (Accordingly the basic properties of matter, such as that of possessing energy, are not explainable.) And an *event* is explained in terms of forces or of other events, e.g. collision or random shuffling. (Accordingly the uniform motion of a body or of a photon in a vacuum are not explainable: only their origin and their eventual deviation from uniform motion are explainable.)

(Note that we have not included statements nor, a fortiori, sets of statements, among the objects that can be explained. To be sure a statement, unless it is an axiom or a definition, may be deduced from other statements. In particular law statements can often be deduced from higher level law statements. But we had agreed to restrict the meaning of "explanation" to subsumption *cum* mechanism. To be sure, sometimes we deduce law statements from higher level formulas, but not every such deduction amounts to an explanation of the corresponding pattern. For example, every equation of motion and every field equation is deducible from some variational principle, but such deduction does not explain motion or field propagation. On the other hand the deduction of a "deterministic" equation of motion or some other pattern from probabilistic laws does amount to an explanation of the "deterministic" pattern. Likewise we explain behavioral regularities in neurophysiological terms. In sum, deduction may or may not correspond to explanation.)

Obviously not everything explainable is worth explaining. The value of an explanation depends on the world view, the state of knowledge, or practical considerations. For example, sometimes we need to explain regularity—e.g. why Johnny has above-average school attendance; at other times anomaly—e.g. why Johnny, who so rarely misses school, is missing today. When we know or suspect that a given process is causal, the observation of accidental departures cries for explanation; but if the process is assumed to be random, then we must explain its regular features. And whereas some students take certain data for granted, others try to explain them. Different people itch in different places at different times.

We have drawn a sharp distinction between explanation and subsumption, suggesting that the latter is little more than description. This distinction is not made in the philosophical literature (except for Bunge, 1967b). The reason for this is that most philosophers have focused on the logical form of explanation, disregarding its epistemological and ontological aspects. This neglect has suggested to some philosophers that the standard view on explanation, found in Popper (1959) and Hempel (1965), is not just incomplete but basically mistaken. In particular it has been suggested that explanation is not a hypothetico-deductive operation but consists in drawing analogies or metaphors, or in empathizing with the actors of the psychological or social phenomena to be explained. These criticisms rest on a confusion between the psychological category of understanding and the methodological category of explanation. As noted in Section 1.1 we may indeed understand via metaphor or *Verstehen*, but explanation is different.

What is true is that most of the explanations offered in ordinary life and even in science and technology are incomplete, and so seem not to match the hypthetico-deductive model. In fact they presuppose (assume tacitly) a number of hypotheses. The most famous of all such incomplete (or enthymematic) arguments is Descartes' "I think, hence I exist (I am alive)". The tacit premise here is "All thinking beings are alive", which, together with the explicit premise "I think", yields the conclusion "I am alive". So although it looks like a proposition it is actually an abbreviated argument.

Incomplete explanations, or *explanations in principle*, abound in all fields of inquiry. Thus the technologist is often content with pointing to "the principle" of his design: he invokes a law statement, or a theory, to explain in outline why his artifact should work. The economist who succeeds in explaining an economic trend does so in principle, not in detail, because his equations (even supposing they were accurate) contain far too many unknown parameters (Hayek, 1955). Likewise the evolutionary biologist can explain in principle the evolution of some biopopulations with the help of the general principles of the synthetic theory of evolution. A full explanation of the evolution of any particular biopopulation would require a precise mathematical model involving mutation probabilities, viabilities, and environmental factors such as the competing populations. However, even a partial explanation is, or can be cast in the form of, a deductive argument: *Pattern and circumstance, ergo explanandum* (fact to be explained).

We conjecture that every explanation, if properly analyzed, will prove to be *incomplete* in failing to explain, with total accuracy, every feature of the object of explanation. This is but one aspect of the incompleteness of all our factual knowledge. Irrationalists should derive no comfort from this postulate, for we also conjecture that every explanation is *perfectible* with the help of further research. Such research generates *explanation chains* of the form *A because B because C*... *M because N*. For example, a girl goes to school because she wants to learn. She wants to learn because she needs a good job. And she needs a good job because her parents cannot support her. An explanation chain is a partially ordered set of explanatory statements of the form "*X* because *Y*". And, as we saw a moment ago, every statement of this type is an enthymeme analyzable into an argument.

Is there a limit to every explanation chain? That is, are there ultimate facts such as Aristotle's Prime Mover? We have no evidence for such ultimates. All we know is that no explanation satisfies forever. For example, Newton explained the planetary orbits in terms of inertia and gravitation. His adversaries, in particular Leibniz and the followers of Descartes, were dissatisfied with Newton's hypothesis of gravitational interaction at a distance: they wished to explain gravitation itself. This explanation came much later with Einstein's field theory of gravity.

Still, there are dogmatists who proclaim that whatever we cannot explain satisfactorily now will remain mysterious forever. One such mystery would be the precise conditions of the "big bang", for the evidence needed to investigate the cause of the primal explosion was destroyed in the explosion itself (Jastrow, 1978). Yet it may well happen that such evidence will eventually be discovered, or even that evidence against the "big bang" hypothesis will be produced. Another alleged perennial mystery is that of consciousness (Eccles, 1978). It is more fruitful to assume instead that this problem had been approached in the wrong ways, namely via theology, philosophy, and mentalistic psychology rather than neuropsychologically. Even if no satisfactory solution to the present mysteries were forthcoming, we would learn more by investigating them than by declaring them to be insoluble mysteries. Research pays more than dogma.

Explanation dissolves mystery but need not remove marvel. The widespread fear that scientific explanation may suppress marvel and our capacity to enjoy nature, art, and human relations, is groundless. On the contrary, (*a*) searching for explanation and finding it is in itself an enjoyable experience; (*b*) by expanding and deepening knowledge, scientific research allows us to marvel at things and processes that were unsuspected before; and (*c*) the practical fruits of science allow millions of people the leisure necessary for enjoying nature, art, and human relations.

Nor does explanation reduce the unfamiliar to the familiar. On the contrary, science explains many familiar phenomena, which we take ordinarily for granted, in esoteric terms. Think of the way meteorology explains the familiar facts of weather, the way chemistry explains the transmogrification of food in the kitchen, the way psychology explains perception, memory and thought, or the way economics attempts to explain inflation. It all sounds, to the layman, very much like the *explicatio obscurum per obscurius* that the modern philosophers attributed to the schoolmen. But at least it is not an *explicatio ignotum per ignotius*: on the contrary, we can now explain the unknown in terms of the known or conjectured. Moreover, obscurity is relative to the subject: in principle anyone can master the technicalities of science. (By the way, the fashionable claim that the use of technicalities by scientists is a manifestation of elitism, which a science for the people should avoid, is sheer obscurantism. There is no deep knowledge without tears. The remedy is not to degrade science but to upgrade education.)

Another widely held belief is that an explanation is nothing but an answer to a why question. Let us test this account with a simple example: Why do people who walk on snow wear snow shoes? Answer: So as not to sink. No doubt, this answer is correct—but it does not explain anything. An explanation requires a more complete answer, such as this one. One sinks in snow the deeper, the harder one presses on it; snow shoes, by distributing the weight over a greater area, decrease the pressure and so also the sinking. In short, although every explanation answers a why (or a how) question, the converse is not true. Moral: Ordinary language is no substitute for conceptual analysis.

We wind up this section with a handful of maxims or rules for explanation.

R1: *Before rushing to explain a fact make sure it is fact not illusion.* (E.g. before explaining spoon bending at a distance establish that it is a fact not a fraud.)

R2: *Explain existents by existents* (established or conjectured) never by nonexistents. (Hence mistrust the explanation of elementary particle events in terms of virtual particles or processes, and of human behavior in terms of disembodied souls or immaterial processes.)

R3: *Explain the observable by the unobservable* (e.g. color changes by chemical reactions) *or the unobservable by the observed* (e.g. societal facts by individual behavior) instead of keeping them separate.

R4: *Mistrust ad hoc explanations*, i.e. explanations with the help of hypotheses that cover only the fact to be explained.

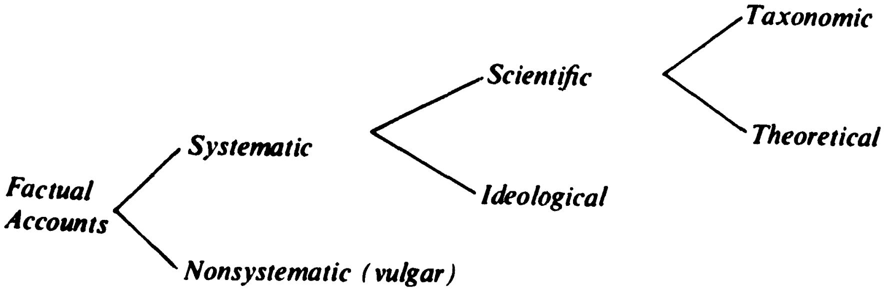
R5: *Mistrust hypotheses and theories that purport to explain everything* (such as psychoanalysis, which professes to explain all human life, and psychoneural dualism, which professes to explain all neural and mental processes).

Only one type of explanation satisfies all of the above rules, namely that performed with the help of scientific theories. Let us then have a look at it.

2. SYSTEMATIC ACCOUNT

2.1. *Vulgar, Ideological, and Scientific Accounts*

Descriptions, subsumptions, explanations, and forecasts will be called collectively *accounts*. Typically, accounts involve hypotheses as well as data; and, whereas some hypotheses are testable and even true, others are just myths. An account can be systematic or nonsystematic. A *systematic account* is one involving some conceptual system: a classification, a theory, or part of either. The system may be scientific or ideological (religious or sociopolitical). If the former, the account will be called *scientific*, if the latter, *ideological*. A nonsystematic account employs only ordinary knowledge (true, half true, or sheer superstition); it may also be called *vulgar*. In short, we have the following classification of accounts of matters of fact:



Examples of each of these categories abound. Thus when explaining a young man's absent-mindedness by his being deeply in love we may be right, but such explanation is nonsystematic: it makes use of a piece of popular wisdom ("People in love tend to act absent-mindedly"), not a conceptual system. The fact that some children resemble some of their long deceased ancestors can be explained either ideologically, by reincarnation, or scientifically, by the genetic hypothesis of recessive genes. Survival after death may be accounted for by the doctrine of the immaterial and immortal soul. In this case there is no rival scientific account, for there can be no evidence for survival after death: to science this is not a fact, hence it does not call for an explanation. What does call for a scientific account is the origin and persistence of the belief.

The typical vulgar account is *ad hoc*, i.e. concocted for the occasion, and *unifactorial*, i.e. it involves a single factor or variable. On the other hand every scientific account is multifactorial, i.e. it involves at least two variables. The reason for such multifactoriality is that every variable is related to at least one other variable, and usually to more than one; so, any change in one of them is bound to affect others. However, because unifactorial accounts are the simplest and have the greatest (though illusory) unifying power, even scientists fall occasionally for them. One instance is the attempt to explain all behavior and all thought in terms of language (Luria, 1961). Another is the cognitivist account of all cognition as rule-directed computation of the same kind as that performed by computers (e.g. Pylyshyn, 1980). A third example of a unifactorial account is the explanation of social change, hence of history, in terms of imitation or innovation, class struggle or political strife, population growth or environmental change, the power of ideas or that of rulers. Seasoned historians know that history is far too complex a process (or bundle of processes) to be explainable by a single factor. They know that social change may start in the economy, or in the culture, or in the polity, and propagate to the other subsystems of society: they know that there is no absolute prime social mover. Likewise biologists explain evolution in a multifactorial fashion: in terms of chance genic variations, geographical isolation, climatic change, ecological catastrophes, natural selection, etc.

Ideological accounts too tend to be unifactorial, but they are all-embracing rather than *ad hoc*: because of this simplicity and unifying power they are as dangerous as they are attractive. Thus political credo X-ism blames all the evils of society on anti-X-ism, and conversely. Astrology attributes every event in human life to the stars. Psychoanalysis blames every psychological trouble on early sexual experiences, whether real or imaginary. Interactionist mind–body dualism (e.g. Popper and Eccles, 1977) accommodates every possible mental event, and so dispenses with all specific theories (of e.g. perception, memory, imagination, and thought) as well as with experiment. (But it explains nothing, for it just states—in an inexact way to boot—that mind and body interact in such a way that they pass one another the buck, without suggesting any interaction mechanism.)

The believer in an ideology has the great advantage, over the vulgar, of being able to offer a single account of every single fact, and of finding it ready made in his system instead of having to search for it. In an open context, on the other hand, every fact can be accounted for in infinitely many ways. Thus if a fact described by a proposition q is observed to happen, then we can deduce that q because p, where p is an arbitrary proposition. (Indeed, the inference "q entails If p then q" is valid in ordinary logic.) Not so in a closed context: here only propositions logically and referentially germane to the given proposition q can be invoked. Moreover in a theory, whether ideological or scientific, there is always at most one explanation for each observation. Therefore, paradoxically, not only the ideologist but also the scientist are spared the agonizing uncertainties of the vulgar: the former because he knows all the answers in advance, the latter because he is confident that he, or someone else, will eventually come up with a satisfactory answer if he investigates the matter. Both are sustained by faith—irrational in the first case, rational in the second.

Scientific accounts are or tend to be systematic and multifactorial, and they avoid the two extremes of the *ad hoc* (or single case) and the all-embracing accounts. Of course there are some extremely general scientific systems, such as the relativistic theory of gravitation and the neo-Darwinian theory of evolution. However, they do not embrace every possible fact in all possible domains, and they do not propose essentially the same account of every fact. (Anything that purports to explain everything actually explains nothing.) Indeed only very specific theories, i.e. models, can account for facts without much further ado. Any account of specifics done with the help of a general scientific theory requires enriching the latter with subsidiary assumptions and data. Let us make a quick study of three kinds of scientific account: description, subsumption, and explanation; prediction will occupy us in Section 4.

A description will be said to be a *systematic scientific description* if it is couched with the help of a scientific system. In particular, a *scientific taxonomic description* is made with the help of some scientific classification, such as one of elementary particles, plants, or economies. *Example*: "Humans evolved from more primitive primates about three million years ago". A *scientific theoretical description* is one made with the help of a scientific theory. It consists in specifying the values of the state variables of a thing as hypothesized by the theory. *Example*: "The electromagnetic wave, of 1 cm long wavelength, hit the two slot screen; the waves emerging from the latter interfered with one another, and were absorbed by a second screen lying 10 m behind the first". Contrary to the empiricist prescription, scientific systems are not built on presystematic descriptions: on the contrary, scientists describe their facts with the help of their conceptual systems.

Caution: Not everything that sounds theoretical is so. Thus over the past few decades a number of scientists have tended to account for facts in the language of the statistical theory of information. They talk about information flows between molecules, the quantity of information locked in a gene, the way the brain processes the incoming information, information networks in society, and so on. Such accounts do not really use the statistical *theory* of information but only its *vocabulary*. In fact, typically they do not identify the sender, the channel and the receiver; they do not assume that the channel is subject to random perturbations; and they do not calculate or measure quantities of information. (As one biologist put it, "it is doubtful whether information theory has offered the experimental biologist anything more than vague insights and beguiling terminology": Johnson, 1970.) Such accounts are therefore *pseudotheoretical.* To be sure they had initially, particularly in genetics, neuroscience, and psychology, some heuristic value. But they have now become obstacles to theorizing in those fields, because they suggest that the theory—namely the statistical information theory—is already there. Besides, even if one were to make use of information theory in those fields one would achieve at most an exact description: information theory is far too general to explain or predict anything. The same holds for other general system theories: the very notion of a general system theory of a particular system, such as a cell, a lake, or a school, is self-contradictory. An extremely general theory is at best a basis for building a specific theory or model. (Recall Ch. 9, Section 1.2.)

Let us now turn to subsumption. As we saw in Section 1.2, a fact (or the proposition describing it) is subsumed under a pattern (or the corresponding proposition) if shown to be a particular case of it. A subsumption will be said to be a *systematic scientific subsumption* if the subsuming construct is a scientific system, such as the periodic table of the elements or the input–output model of an economic system. In particular, a *scientific taxonomic subsumption* is one where the subsuming construct is a scientific classification. *Example*: "Copper, silver and gold are simple metals". A *scientific theoretical subsumption* is a subsumption under a scientific theory, i.e. such that the explanatory premises are theoretical formulas and data. For example, every instance of light refraction falls under Snell's law. In particular this law, together with the values of the angle of incidence and the refractive indices of the two adjoining media, entails the value of the angle refraction and thus accounts for it. But, because the Snell law is phenomenological (or black box), nothing gets properly explained in this way: the account looks very much like a description, except that it involves a deduction.

(The logic of subsumption boils down to the following. Let $\mathcal{T}$ be a scientific theory in a context $\mathcal{C} = \langle P, Q, R \rangle$, i.e. such that (*a*) the set of formulas of $\mathcal{T}$ is a subset of P, and (*b*) some formulas in $\mathcal{T}$ refer to entities in R. Further, let p and e be propositions in P but not in $\mathcal{T}$, and such that (*a*) p describes a fact or class of facts f involving entities in R, and (*b*) e is a bit of empirical evidence relevant to p (and therefore referring to R's or to things, such as measuring instruments, that are somehow connected with R's, as is the case with telescopes aiming at stars). We stipulate that $\mathcal{T}$ *subsumes* f iff there is in P, but not in $\mathcal{T}$, a (possibly empty) set S of subsidiary assumptions such that p follows from $\mathcal{T}$, S and e.)

The fact being subsumed may be some thing being in a given state or undergoing a given change. If a whole class of facts is being subsumed, then the proposition that is being derived with the help of the accounting theory is a hypothesis not included in exactly the same form among the general principles of the theory. For example, the various laws of geometrical optics—rectilinear propagation in a homogeneous medium, mutual independence of the components of a light beam, reflection and refraction of rays—are subsumed under wave optics. In geometrical optics the refraction index is an irreducible phenomenological parameter; in wave optics it is a kinematical parameter, namely the ratio of the velocities of propagation in the two media. In electromagnetic optics the refractive index is the former as well as a function of the molar electric and magnetic properties of matter; the index is explained properly only by the theory of the atomic structure of matter.

We construe explanation as a particular case of subsumption, namely as *subsumption under a mechanismic* (or translucid box) *theory*. Indeed we stipulate that a fact or class of facts F is *explained* by a theory $\mathcal{T}$ iff (a) f is subsumed under $\mathcal{T}$ and (b) $\mathcal{T}$ is mechanismic (instead of phenomenological). This definition covers the explanation of factual items of all kinds: properties (hence states) of things, events (changes) in things, and patterns of things, such as trends and even laws. Thus we say that the theory of electron dispersion explains the refractive index of quartz; that the electromagnetic theory of light explains the refraction process; that quantum mechanics explains the formation and breakdown of molecules; and that economic theory is supposed to (though it is doubtful that it does) explain the inflation characteristic of the 1970s.

Note the following points. First, every explanation is a subsumption but the converse is false. Second, explanation is richer than subsumption, which is only a special case of deduction: explanation tells us not only what happens but also how it happens. Therefore not all theoretical models are explanatory. In particular, a mere mathematical representation of a set of facts, even if true, does not explain anything. Third, whereas in physics, chemistry, and biology, explanation is nomological (i.e. involves law statements), from psychology upwards rules and evaluations may be involved as well. Thus we may explain somebody's action A by saying that A

causes B (*law*), the individual knows this and values B (*valuation*), and he has adopted the *rule* or maxim that he will always endeavor to attain what he values. Fourth, theories about matters of fact contain law statements and they may also contain valuations and rules, but they do not contain trends or changes in trends. Far from explaining anything, trends and their changes are objects to be explained in terms of laws, valuations, rules, or circumstances. For example, the steady increase in the international price of crude oil is explainable by the decision of the OPEC countries to stop financing the affluence of the OECD countries. And the growth of the tertiary sector of the economy (i.e. the services) is explainable by the increasing importance of technology in agriculture and industry, as well as by the passing of welfare legislation.

I submit that the above explicates what scientists usually mean by 'explanation', namely an account in terms of some mechanism or other, be it causal or stochastic, physical, biological, social, or other. However, once in a while pseudoexplanations appear in the scientific literature. For example, a biologist may lapse into teleology when forgetting that no modern biological theory (in particular no mathematical model) contains the concept of goal or final cause. Or he may be tempted to explain morphogenesis in terms of "morphogenetic fields", ignoring that, in order to speak literally about a field, there must be a field theory with definite and testable field equations. Likewise the computer scientist and the cognitivist (or functionalist) psychologist may feel that they explain the mind when translating mentalistic psychological descriptions into the language of computer science—e.g. when they translate 'x recalled y' into 'x retrieved y from his memory bank'. Translation into one's professional jargon produces familiarity not explanation.

We have called 'theoretical subsumption' what most philosophers call 'explanation'. The classical account of that operation, though one different from ours, is that of Hempel and Oppenheim (1948), usually called 'the deductive-nomological (or D-N) model of explanation'. It has been criticized in various ways, some correct, others incorrect. Ordinary language philosophers have complained that in ordinary language one often calls 'explanation' statements of the form "q because p", which are not logical arguments and need not mention any law statements, so that they are true of false. This criticism, like that of the use of logic in philosophical analysis generally, misses the point: philosophers of science are interested in a technical concept of explanation, which may be absent from ordinary knowledge considerations but happens to occur in scientific contexts.

A relevant criticism is that the Popper–Hempel–Oppenheim relation of explainability holds between almost any general hypothesis and almost any singular sentence (Eberle, Kaplan and Montague, 1961). Consequently there is no great merit in subsumption—not more than in curve fitting, a close relative. Weightier criticisms than this can be raised against the D-N "model" of explanation. One is that it usually requires the explaining premises to be true. This requirement is unrealistic, for in science and technology total truth is hard to come by: our hypotheses and theories are at best partially true, and sometimes our data too are far off the mark—to the point that we may seek to subsume "facts" that, under closer examination, prove to be nonexistent. (Strangely enough most of the repairs proposed to the D-N account of subsumption keep the condition that the explaining premises be true.) A second defect of the D-N "model" is that it is about an open-context operation: it does not require the explanatory premises to belong to theories (hypothetico-deductive systems). But, as we have seen, in an open context almost anything may be accounted for in a number of alternative ways: it is only relative to a definite conceptual system that one can speak of *the* subsumption, or *the* explanation, of a fact. Thirdly, the D-N "model" does not mention the subsidiary assumptions that occur in almost every systematic account of facts but are not part of the theory itself—e.g. the composition and structure of the system to be accounted for. (This oversight may be due to the well-known fact that most philosophers of science think of classical particle mechanics when they write about theories.)

But the most damaging criticism that can be made of the D-N "model" of explanation is one that is seldom voiced, namely that it is concerned with theoretical subsumption, not with genuine explanation: it ignores the mechanisms of things. In this regard—not with regard to the logical apparatus—it is less satisfactory than the classical account of explanation, from Aristotle to Meyerson (1921). According to this alternative view we explain events by their causes, and if we do not know the causes then we may describe or subsume but not explain. As Whewell (1847, P. I, p. 652) put it, "No sound theory without Aetiology". (For an exposition and criticism see Bunge (1959a).) This doctrine became obsolete the moment probabilistic theories began to invade science and technology. We submit that a genuine explanation is one that invokes some mechanism or other, whether causal or stochastic (probabilistic). We shall devote the next section to these two modes of explanation.

We close this section with some thoughts on the power of theoretical accounts in general, be they descriptions, subsumptions, explanations, or forecasts. Two rival accounts of the same fact, or class of facts, may not be equivalent: one of them may be better than the other. Because rationalists are supposed to justify their valuations, let us explicate the notion of preference involved in the statement schema "Account X of fact f is preferable to account Y of f". We shall say that a theoretical account is the better, the wider its coverage of facts, the more accurate, and the deeper.

(More precisely, let A_1 and A_2 be two accounts the reference classes of which have a nonempty intersection R. We stipulate that (*a*) A_1 has a greater *range* than A_2 iff the hypotheses of A_1 are more general (less *ad hoc*) than those of A_2; (*b*) A_1 has a greater *accuracy* than A_2 iff A_1 involves truer premises than A_2 and, in the case of prediction, A_1 scores better (is better confirmed) than A_2; and (*c*) A_1 is *deeper* than A_2 iff A_1 involves more levels of organization than A_2. These three aspects are mutually unrelated: depth is compatible with either generality or specificity, as well as with accuracy or inaccuracy. The *best* of two roughly equally accurate and equally general accounts is the deeper, and the best of two equally deep accounts is the more accurate and general one.)

2.2. *Basic Explanation Types*

We have stipulated that, unlike a description, a subsumption, or a prediction, an explanation invokes some mechanism or other (Section 2.1). We may distinguish five basic or pure types of mechanism or mode of becoming: causal, stochastic, synergic or cooperative, dialectical or conflictive, and teleological (Bunge, 1981a). These five pure types may combine by twos or more to form a total of 26 mixed types. So, there are at least 31 types of mechanism, or modes of becoming, hence 31 types of theories and models, and therefore 31 types of explanation. This number would decrease if it were proved that some of the modes of becoming which we have regarded as basic are reducible to others; but future research might also increase the number of basic types of mechanism.

It seems safe to assume that the pure types occur in reality only approximately: that only mixed types of becoming occur in nature and society (Bunge, 1959a). For example, the processes accounted for by the quantum theories are causal as well as stochastic, at least wherever forces (or potentials) are involved (Ch. 8, Section 3.1); every realistic theory of systems of any kind must take into account cooperation (in system formation and maintenance) as well as conflict (among system components or between them and environmental items); evolutionary processes involve causation, chance, cooperation, and competition; and human social processes involve all five basic types. However, most theories and theoretical models in science and technology involve only one or two basic types of mechanism. This restriction is sometimes due to the fact that there is often only one, or a couple, of overriding mechanisms; at other times it is merely the result of ignorance or even prejudice. Let us make a quick review of such models and the corresponding explanations.

Causal mechanisms, and the accompanying explanations, are probably the most familiar. There is causation if some properties of a thing change under the influence of external events. The former event (or process) is called 'effect', and the latter 'cause'. (These concepts can be elucidated in terms of the notion of history of a thing: the total effect is the distortion in its history due to external influences. See Bunge, 1982.) The best known example of a causal theory is automata theory. Indeed a deterministic automaton stays in a given state unless it accepts an input, and when it does it jumps to another state. No input, no change of state and therefore no output. (Formally: the next state function M, that maps the set of ordered pairs $\langle$state, input$\rangle$ into the set of states, satisfies the condition $M(s,0)=s$, where s is an arbitrary state and 0 the null input.) Only such changes of state are in need of explanation, and they are explained in terms of inputs and previous internal states. Similarly in mechanics all causes are forces or constraints, and the corresponding effects are deviations from uniform and straight line motion, or changes in inner stresses. Only such deviations, not motion itself, are to be explained. (However, mechanics is not a purely causal theory, if only because, unlike automata theory, it involves self-movement in the guise of inertia: see Bunge, 1959a.) Similar causal or partially causal mechanisms, some mechanical and others not, are hypothesized in all fields of factual research.

All events involving large scale systems have joint multiple causes. There are two ways of disentangling such causal factors, i.e. of imputing the observed or conjectured effect to the various causes at play. One is to "freeze" experimentally all factors but one, by using such procedures as insulation and compartmentalization—which are not always practicable. The other method is to perform a theoretical analysis. For example, the radio waves emitted by radio stars lying behind the sun are deflected by the latter. This deflection is due partly to refraction by the solar atmosphere (corona) and partly to the solar gravitational field. The way to separate these effects is to use the knowledge that refraction depends on wave length, so that the total deflection equals the sum of the gravitational deflection and a wavelength-dependent deviation. By measuring the total deflection for different wavelengths one can identify the gravitational part of the total effect.

The philosophical literature on causality is rather meagre both quantitatively and qualitatively. (For a review see Bunge, 1982.) The two most popular views on causation are the logical and the probabilistic ones, neither of which is adequate. According to the former the causal relation is faithfully represented by a conditional proposition relating the cause to its effect. On this view a cause is just a sufficient (or perhaps necessary and sufficient) condition for its effect. This view is wrong for two reasons: one is that causes are events not reasons, not even sufficient reasons. (See Bunge, 1959a.) Another is that, given any event, one may invent any number of "causes" capable of "explaining" it without violating logic, though in most cases science will be violated. Indeed, a proposition *e* describing the given effect entails $\ulcorner e$ or not-$c\urcorner$, where *c* is an arbitrary proposition describing any old "cause"; but $\ulcorner e$ or not-$c\urcorner$ is equivalent to $\ulcorner c \Rightarrow e\urcorner$. So, causal "explanations" out of context are cheap, hence we should not care for them. What science does cherish is systematic or theoretical explanations, whether or not they involve causal laws. In other words, only if $\ulcorner c \Rightarrow e\urcorner$ is a law statement (hence one included in a confirmed theory), does *c* explain *e*.

The probabilistic view of causation regards the latter as a particular case of a probabilistic relation. (See Suppes, 1970.) The heart of this view is the definition: "*c is the cause of e* $=_{df}$ The probability of *e* given *c* equals 1", or some weaker version, such as "*c is a cause of e* $=_{df}$ The probability of *e* given *c* is greater than the absolute probability of *e*". Two trivial counterexamples are enough to ruin this view. The probability of my dying, given that I was born, equals unity—yet my birth could not possibly be regarded as the cause of my death. Second counterexample: The probability of rain, given a sudden drop in the barometer reading, is greater than the probability of rain *tout court*—yet the barometer reading is just an indicator of rain, not its cause. (For further criticisms see Bunge, 1973e.) In sum, causation is not definable in terms of probability. Nor is the converse reduction of probability to causation possible. What is possible and useful is to relate the two concepts.

We use the concepts of causation and probability on a par in science and technology. Thus geneticists speak of the probability that radiation of a given kind will cause a certain mutation. In the quantum theories we compute not only probabilities of spontaneous (uncaused) events, such as the spontaneous radiative decay of atoms. We also compute the probabilities of caused events, e.g. that a given external perturbation will cause the atom to emit a photon of a given frequency. The concepts of cause and effect are retained in the quantum theories but they are related in a probabilistic, not in a causal way. (Recall Ch. 8, Section 3.1.) In general, in the context of stochastic theories, instead of asking "Does *c* cause *e*?", we ask "What is the probability that *c* causes *e*?" Correspondingly, pointing to the cause is necessary but not sufficient to explain: we must add the probability of its efficiency. In other words, we need two concepts instead of one: those of cause and of efficiency of a cause, which is in turn reduced to that of probability (that the cause will produce its effect).

A probabilistic subsumption is one from premises at least one of which is a probabilistic law (not just a statistical generalization). Thus given a velocity distribution we can infer the average velocity and the spread around that average. (Actually we can infer infinitely many statistical parameters, namely all the moments of the distribution.) This will not explain anything unless it is explicitly stated that the distribution is one of entities moving randomly. The least a probabilistic subsumption does is to show events of a certain kind to be possible, i.e. to have a nonvanishing probability. Such account is of course far poorer, and therefore less satisfying, than the proposal of a definite random mechanism, i.e. a stochastic explanation proper.

Consider the following examples of random mechanisms. The inner face of a window pane becomes fogged in cold days. This process (or the corresponding proposition) can be subsumed under a rate equation representing the increase in thickness of the layer of water vapor on the pane. But this does not explain anything. The explanation is that the water molecules and droplets move randomly about the room and arrive independently from one another to the cold pane, to which they transfer their kinetic energy. This uniformity, and the huge numbers, explain the uniformity of the fogging. Second example (P. and T. Ehrenfest): A dog ridden with fleas meets a clean dog. After a while each dog has approximately the same number of fleas: the two-dog system has attained the equilibrium state. The explanation is that the fleas jump more or less at random from one dog to the other until, in the end, about equal numbers of fleas jump in both directions. Third case: the nearly equal distribution of sexes in humans and other animals is explained by the chromosome composition and the random shuffling, at fertilization, of the genes composing them.

A last example, which is also one of exactification. We all know that, when a message is transmitted along a noisy channel, such as a long distance telephone line, the receiver is likely to fail to understand some words. As the message is repeated, its intelligibility increases; intuitively one expects its intelligibility to be proportional to the number of repetitions. The stochastic model that explains this process boils down to the following. Suppose a given message is composed of N words, and pretend that all of them have the same probability p of being understood by the receiver. The expected number of words that are identified correctly on a first presentation is Np; consequently the number of failures is $(1-p)N$. If these wrongly understood words are repeated, we may expect to understand, on the average, $p(1-p)N$ of them. Therefore after two presentations the total expected number of correctly understood words will be $pN+p(1-p)N$; hence the expected ratio of understood words to total number of words is $p+p(1-p)=1-(1-p)^2$. By iteration we find that, after the nth presentation of the message, the cumulative fraction of correctly understood words, or total intelligibility, is $I_n=1-(1-p)^n$. As suspected, this number is close to np. (An obvious generalization is to unequally probable words. And a deeper model would treat p not as an ultimate but as a function of certain properties of both channel and receiver.)

In all cases of probabilistic explanation what is explained is some statistical regularity, such as an average or a correlation (e.g. a trend). Thus we explain the fact that nearly all individuals in a crowded sidewalk, and nearly all cars on a very busy road, have roughly the same speed, by pointing out that a faster pedestrian (or car) would be stopped, and a slower one would be pushed. (The theoretical problem is: Given the average $\bar{F}$ of a certain magnitude F, conjecture some probability distribution p of F with mean $\bar{F}$. This is an inverse problem and therefore has no unique solution. The direct problem, which has a unique solution, is: Given p compute $\bar{F}$.) What holds for averages holds, *mutatis mutandis*, for spreads and other statistical parameters. In the case of statistical correlations we may try either of the following tactics. One is to assume an underlying causal relation, e.g. via a third factor upon which the two given variables depend. If this move fails one may try a stochastic model including one or more probability distributions allowing one to compute the observed correlations. Comparison with the data will either confirm the model or call for its modification—or for a new, more extended or more precise run of observations. (The correlation may have been accidental.)

Unlike causation and design, chance is often regarded as unintelligible, hence stochastic models as merely temporary devices incapable of explaining anything. Correspondingly only causal (and possibly also teleological) explanations are regarded as genuine. (Thus Salmon (1977, p. 162): "To give a scientific explanation is to show how events and statistical regularities fit into the causal network of the world".) But after more than fifty years of highly successful quantum theories—and thirty of failure to produce any worthy rivals containing only "hidden variables"—it is time to take chance as a basic mode of becoming. In fact these theories, in the realist interpretation, assume that every single entity, be it a particle or a field quantum, possesses ("obeys") objective probabilistic laws, such as position and momentum distributions (Bunge, 1967c). This type of chance is radically different from the accidental crossing of two or more initially independent causal lines—the kind of chance known to the Stoic Chrysippus and inherent in classical statistical mechanics. In the quantum theories we understand events in terms of an interplay of causation and chance.

The philosophical literature on probabilistic explanation is disappointing: it simply does not concern this type of explanation. Thus Hempel (1965, Ch. 12), in a pioneering study on the matter, made an assertion that has been repeated uncritically by a number of other philosophers. He stated that what he called "the inductive statistical" model of explanation differs from the "deductive-nomological" one in two respects. First, the laws are "statistical rather than universal"; second, the explanandum follows from the explanans with high probability rather than deductively. These two propositions are false.

The first proposition involves a confusion between a probability *law*, such as the Maxwell–Boltzmann law or the Schrödinger equation, and a mere statistical generalization such as "f percent of the population of X are illiterate". The stochastic laws occurring in science and technology contain universal quantifiers ranging over their referents, instants of time, etc. (For example, "For all systems of particles in equilibrium, the probability density is proportional to exp $(-E/kT)$".) As for the second assertion we are discussing, all the inferences made in stochastic theories or models are strictly deductive, for they consist either in proofs or in computations. Thus averages are computed from distributions and the definition of an average. In addition to ignoring the probabilistic laws of science and technology, Hempel has confused probability theory (a chapter of pure mathematics), mathematical statistics (an application of the former), and theories of random processes (distributed among the various chapters of science and technology). I have singled out Hempel's study not because it is the worst but because it is the clearest and it has inspired an uncounted number of equally wrong-headed treatments of an important problem.

Now a few words about synergy and dialectics, of which more elsewhere (Bunge, 1981a). Every process of accretion, clumping, self-assembly, or merger, be it of atoms, molecules, organisms, or social systems, is one of cooperation—mostly unwitting to be sure. Thus we explain the formation of biomolecules light and heavy as a self-assembly process, and in turn explain this process in terms of physical forces and chemical bonds. Likewise we explain the breakdown of systems on all levels in terms of conflicts among their components, or among these and environmental things. In turn, a conflict may be explained or analyzed as some dissociation process such as receding motion or competition for a resource.

Both modes of becoming or change mechanisms, cooperation and competition, coexist and intertwine on all levels (Bunge, 1976). Consider two simultaneous chemical reactions of the forms "$A + B \rightarrow C$" and "$B + D \rightarrow E$". In each of these processes the reactants may be said to cooperate to form the reaction product; but A competes with D for B. Hence this is a case of mixed mechanism. (The entire chemical kinetics of systems of reactions is concerned with cooperation-competition processes.) Certainly, saying that C is the outcome of the cooperation (or competition) of A with B explains the emergence of C, but in a superficial manner. The cooperation (or competition) itself can in turn be explained, at least in principle, in terms of forces, constraints, interests, or what have you.

The last type of mechanism in our list is goal-seeking (or teleological) behavior. Thus when dealing with higher vertebrates we often account for animal A's doing B by saying that B serves to attain C, which we assume tacitly to be of value to A. The explicit argument is: "A expects that doing B will bring forth or favor the occurrence of C. Now, A values C. Hence A does B." This is not a deductive argument. It is not even intuitively correct, for A might abstain from doing B, although it values the outcome C, because it is prevented from acting, or because it lacks the means, the energy, or the courage to act. To be sure, we may complete the account by adding that A is free and capable of and willing to do B to attain C. But even so completed the conclusion that A does B does not follow deductively from the premises. So, teleological accounts are not arguments proper, hence they do not qualify as subsumptions, let alone as explanations. In order to transform them into such we need something like a calculus of means and ends yielding the desired conclusions from premises consisting in law statements, rules, and value judgments. (See Bunge, 1977e.) As long as no satisfactory calculus of this kind is available we should avoid teleological accounts, or at least abstain from attributing to them any explanatory power.

3. UNIFICATION

3.1. *Reduction*

Genic variation has been explained as change in the composition or in the structure of genetic material, i.e. DNA molecules. This new account of a previously known process has enabled biologists to effect the reduction of a part of genetics to molecular biology (or biochemistry). In this case the key to understanding has been reduction; in others it is integration. Thus bioevolution is not understandable on the molecular level alone, but calls for a merger of genetics (both molecular and populational), anatomy, physiology, ecology, biogeography, palaeontology and systematics—actually all the branches of biology. In this section we shall study reduction, a much misunderstood operation; we shall leave integration, a generally ignored operation, for the next section.

We can reduce concepts, propositions, and theories. In some cases reduction results in a deeper understanding, in all cases it unifies fields of inquiry. Thus the identification of light with electromagnetic radiation gave us a deeper understanding of light and brought about the unification of two previously separate fields of inquiry. The identification of mental states with brain states of a certain kind is producing not only understanding but also the merger of psychology with neurophysiology, and of psychiatry with neurology. And the identification of historical processes with social changes elucidates history and invites the rapprochement of all the social sciences. Far from impoverishing, such unifications enrich both the reducing and the reduced field of inquiry. However, as we shall see in the next section, integration is no less valuable a device for attaining the unity of knowledge.

Let us start with concept reduction. Table 10.1 exhibits a handful of famous cases of reduction in modern factual science. Every one of them can be understood as a case of concept reduction, which in turn is reducible to a special case of definition. Indeed we stipulate that, if concepts A and B belong to contexts (e.g. theories) $\mathcal{C}_A$ and $\mathcal{C}_B$ respectively, then A is *reducible to* B *in* $\mathcal{C}_B$ if and only if A is definable in terms of B and other concepts of $\mathcal{C}_B$. We call such definition a *reductive definition*, or simply

TABLE 10.1
Some illustrious cases of concept reduction

Reduced Concept	*Reducing Concept*
Heat	Random atomic or molecular motion
Light	Electromagnetic radiation
Chemical reaction	Atomic or molecular combination, dissociation, or substitution
Gene	Segment of DNA molecule
Metabolism	Sequence of biochemical reactions
Goal directed behavior	Negative feedback controlled process
Mental state	State of a plastic neuronal system
History	Process of social change

(concept) *reduction*. Thus the first line of Table 10.1 reads: "The concept of heat (in thermodynamics) is reduced to the concept of random atomic or molecular motion (in statistical mechanics)". Or, to put it in the linguistic mode: "The expressions 'heat' and 'random atomic or molecular motion' have the same denotation in the language of statistical mechanics." Every reductive definition identifies concepts (not things or attributes) that had been treated separately before. This explains its being commonly called a 'bridge formula'.

Our regarding bridge formulas as definitions, hence as identities (Vol. 1, Ch. 10), does not entail that they are arbitrary or conventional. They are definitions *in the new context* (the reducing one). But when first proposed they are *hypotheses* and, as such, they have to win acceptance on theoretical or empirical grounds. (Many an attempt at reduction has failed: we honor only success.) But once the more powerful body of knowledge has passed the tests, the bridge formulas, which were initially hypotheses, are incorporated as intratheoretical definitions. Thus, regardless of the way "light ray" was defined before, one defines it now as the normal to the wave fronts of an electromagnetic radiation field.

The above discussion sheds light on the current controversy over the status of the bridge formulas. Some philosophers admit that they are identities but call them 'contingent identities' (Kripke, 1971); others regard them as identities of things or properties (Causey, 1977); finally others regard them as hypotheses and even laws (Nagel, 1961). The former reason that the reductive definitions, unlike the necessary identities of logic, may not hold in all possible worlds. It must be supposed they have privileged information about such imaginary worlds; in particular they must know that logic holds in all of them, whereas in some of them heat is not random atomic or molecular motion. Having no access to such wondrous information I shall regard reductive definitions as strict identities of concepts. They cannot assert the identity of things or of properties because, if two factual items are the same, then they are one.

As for the view that bridge formulas are laws on a par with laws of motion and others, it may have been suggested by the way they are originally introduced—namely as hypotheses—not by the role they perform in mature theories. Surely it is not a law of nature that the internal pressure of a gas is identical with the average molecular momentum transfer; nor is it a law of nature that combustion is fast oxydation. These are concept identifications: they have no ontic counterpart and have therefore a purely epistemological status. (An omniscient being would dispense with reductive definitions.) To put it into the linguistic mode: a reductive definition effects the translation of an expression of one language into another.

The reduction of propositions follows from the reduction of concepts. Thus "We inherit genes" is reducible to "We inherit segments of DNA molecules". Truth values are preserved under such transformations. Not so meanings, for meaning is contextual (Vol. 2, Ch. 7). Thus the sense of "heat" in classical thermodynamics is the set of all its logical relatives, which is not the same as the set of the logical relatives of "random atomic or molecular motion" in statistical mechanics.

The reducibility of theories (hypothetico-deductive systems) is more complicated. To begin with we distinguish reduction from restriction. Thus the restriction of classical mechanics to point particles is particle mechanics. The latter is a subtheory of the former, obtained by setting the mass density equal to a point-like distribution (a delta), and by discarding the stress tensor and the boundary conditions. (Cf. Bunge, 1967c.) The general definition is this: Let $\mathcal{T}_1$ be a theory with reference class or domain R. Then $\mathcal{T}_2$ is the *restriction* of $\mathcal{T}_1$ to S, where S is a proper subset of R, iff $\mathcal{T}_2$ is a subtheory of $\mathcal{T}_1$ and refers only to the members of S. (For the concept of subtheory see Ch. 9, Section 1.2.) Unlike reduction, restriction does not involve reductive definitions. (Restriction can be characterized in a formal way. Let Q_1 and Q_2 be the sets of basic or undefined predicates of $\mathcal{T}_1$ and $\mathcal{T}_2$ respectively. Then (*a*) Q_2 is a proper subset of Q_1—i.e. some predicates in $\mathcal{T}_1$ have no counterpart in $\mathcal{T}_2$; (*b*) every function in Q_2 is the restriction of the corresponding function in Q_1 to the reference class S of

$\mathcal{T}_2$, or its value in some limit. Thus by setting $c = \infty$ in a relativistic theory, or $h = 0$ in a quantum theory, the corresponding classical theory results.)

Unlike theory restriction, theory reduction involves reductive definitions acting as bridges between the new or reducing theory, on the one hand, and the old or reduced theory on the other. In the most interesting cases, usually ignored in the philosophical literature, reduction involves also additional assumptions not contained in the reducing theory. For example, acoustics is reducible to the theory of elasticity with the help of the reductive definition of "sound" as "wave propagating in an elastic medium". On the other hand the reduction of ray acoustics to general (or wave) acoustics requires the assumption that the wavelengths be small enough so that diffraction is negligible. (The relation between wave and ray optics is parallel.) Likewise the law of ideal gases ($pV = kT$) is deducible from the theory of particle mechanics enriched not only with reductive definitions of "p" and "T" but also with the assumption of molecular chaos. (Incidentally, such reduction has a bonus: it interprets in atomistic terms the phenomenological constant occurring in the phenomenological law.) We shall speak therefore of two kinds of reduction: *strong* or full, and *weak* or partial. Whereas strong theory reduction involves only enriching the reducing theory with reductive definitions, weak theory reduction requires, in addition, subsidiary hypotheses not contained in the reducing theory.

(We summarize the preceding discussion in the following definition. Let $\mathcal{T}_1$ and $\mathcal{T}_2$ be two theories with overlapping reference classes, D a nonempty set of reductive definitions, and A a nonempty set of hypotheses not included in either $\mathcal{T}_1$ or $\mathcal{T}_2$ but couched in the language of $\mathcal{T}_1$. Then (*a*) $\mathcal{T}_2$ is *fully* (or *strongly*) *reducible* to $\mathcal{T}_1$ iff the union of $\mathcal{T}_1$ and D entails $\mathcal{T}_2$; and (*b*) $\mathcal{T}_2$ is *partially* (or *weakly*) reducible to $\mathcal{T}_1$ iff $\mathcal{T}_2$ follows logically from the union of $\mathcal{T}_1$, D, and A. Moreover we shall say that $\mathcal{T}_1$ *helps explain* $\mathcal{T}_2$ iff $\mathcal{T}_1$ is mechanismic and $\mathcal{T}_2$ is phenomenological, and $\mathcal{T}_2$ is fully or partially reducible to $\mathcal{T}_1$.)

Theory restriction is straightforward. (However, it requires more than mathematical competence, namely the knowledge and intuition necessary to choose intelligently what to restrict.) Theory reduction is far more complicated: it requires familiarity with the two theories concerned, as well as an ability to grasp analogies between facts of different appearance. And partial reduction requires, in addition, the imagination that goes into the invention of the suitable additional hypotheses. Think of the ingenuity that went into the construction of modern solid state theory, which is based on quantum mechanics but is neither a subtheory nor a restriction of the latter. More on this below.

The most interesting philosophical feature of reduction is that it explains the emergence of novelty, i.e. the formation of things possessing properties not shared by their components. Scientists are often suspicious of the concept of emergence for regarding it as obscure. However, it can be defined in exact terms, namely as follows. Let s be a system with A-composition, i.e. the components of which (at a given level of analysis) are of type A, where A is a natural kind such as the collection of all atoms, or cells, or societies. If P is a property of s, then P is *emergent* with respect to A if, and only if, no component of type A possesses P; otherwise P is a *resultant* property with respect to A. *Example*: Neural connectivity is not a property of individual neurons but of neuronal systems. And mental activity is not a process in an individual neuron but one in highly complex neuronal systems with variable connectivity. Hence a neurophysiological explanation of perception, memory, or intelligence, will require not only knowledge of individual neurons but also data and hypotheses concerning the interactions among neurons to produce neuronal systems (psychons) endowed with the emergent properties which we call 'mental'. In short, sometimes emergence can be explained by reduction, i.e. in terms of lower level entities and their interactions.

Emergence is not exclusive of the higher levels of organization of matter but occurs on all levels. Consider three things, A, B, and C, of different kinds and capable of assembling into three component systems. In principle six different linear systems are possible, among them ABC and BCA. The structure (order, configuration, pattern of interactions) of the system will certainly be determined by the interactions among its components. But the structure of a system is an emergent property of it, one that neither of its components possesses, and therefore one that could not have been predicted from a knowledge of the components alone.

Consider two specific examples, and in the first place the formation of one of the simplest systems we know of, namely a hydrogen atom. It is composed of a proton and an electron interacting via an electric field. To a first approximation we may disregard its environment, i.e. we may assume that it is placed in a perfect dark vacuum. The application of quantum mechanics to the study of this system explains the emergent as well as the resultant properties of this system. (The explanatory schema is that of a partial reduction: quantum mechanics, enriched with a set of subsidiary assumptions concerning the composition and structure of the system, entails the explanandum. The resulting conceptual system is a bound theoretical model in the sense of Ch. 9, Section 1.2.) The resultant properties of the system are the total mass, charge, angular momentum, and spin. The emergent properties are the discrete energy spectrum (a denumerable infinity of energy states), the probabilities of radiative decay and excitation, and the corresponding probabilities of transition among the various energy levels. None of these properties is possessed by either of the components of the system.

One of the most spectacular successes of the reductionist program is contemporary solid state physics. Consider a length of copper wire. Every one of the atoms that composes it can be accounted for, in principle, by the quantum theory of atoms. However, the body composed of these atoms has bulk properties, such as electrical and thermal conductivity, malleability, and brilliance, which are emergent with respect to the component atoms. These properties are not represented in the quantum theory of atoms, hence they cannot be explained by the latter without further ado. However, solid state physics explains those emergent properties on the basis of quantum mechanics, namely adding to it certain hypotheses concerning the copper crystal lattice, the electrons wandering through it, and the interactions among the copper ions and the electrons moving about in the lattice. Clearly, then, this reduction is of the partial or weak kind. So is the reduction of genetics to molecular biology.

From an ontological viewpoint there are two kinds of reduction: micro and macro. *Microreduction*, or bottom-up analysis, takes the elementary components for granted and attempts to explain the whole in terms of the former and their mutual actions. On the other hand *macroreduction*, or top-down analysis, takes the whole for granted and tries to explain the behavior of its parts in terms of the former. Both accounts have been known from Antiquity: microreduction to the Greek and Indian atomists, macroreduction to Aristotle. Of the two reductionist programs microreductionism has proved by far the more fertile.

The reasons for the microreduction (or atomistic) program are three. One is the ontological hypothesis that all macrosystems are composed of microphysical things such as atoms. Another reason is epistemological, namely that, if one knows the way the components of a system behave, one should be able to infer how the system as a whole behaves. The third reason is methodological: the laws of the microcomponents are supposed to be simpler, hence more readily known, than the laws of the systems they compose. The first reason is legitimate, but we have known this only since the beginning of our century. The second reason holds only in part, for in order to account for the emergent properties of a whole we need to know not only its components but also the mode of their composition (i.e. the system structure) as well as its environment. And the third reason turned out to be false: in fact most known macrolaws are simpler than the microlaws. (Think of the quantum theories *vis-à-vis* their classical counterparts.) The reasons for this greater simplicity of macrolaws are the following: (*a*) a system behaves as a unit in certain respects; (*b*) some of the random fluctuations in the components either cancel out or are unimportant at the macrolevel, and (*c*) the system can be freer than its components, every one of which interacts strongly with other components—for otherwise there would be no system.

The first of the above-mentioned reasons suffices to explain the sensational success of the microreduction program. However, in many cases microreduction is insufficient and must be supplemented with the macroreduction perspective. Thus to explain the peculiar properties of the surface of a liquid we need to know that it is the boundary of a system; to explain the activities of the motor cortex we need to know that it controls the limbs; to explain a machine we need not only a knowledge of its parts but also of its global functions. In all these cases a synthesis of micro and macroreduction is called for.

Theory reduction is one way of explaining emergence. (It is not the only way: in some cases one succeeds in building from scratch a theory explaining the formation of systems of some kind.) However, philosophers concerned with preserving the marvellous variety of reality fear that reduction may eliminate emergence. This fear betrays uncertainty about emergence itself and misunderstanding about explanation. The explanation of a fact does not eliminate it. (What we do eliminate sometimes is nonfacts, i.e. false conjectures about nonexistent facts, as when we explain the fact that two people happened to think of the same object at the same time as a coincidence instead of as evidence for telepathy.) Far from denying the existence of different levels of organization, reduction relates them: i.e. it helps understand the level structure of reality instead of leveling it down or up (Bunge, 1977b).

In any event, the reduction operation has a number of aspects in addition to the logical one, which is almost exclusively that studied in the philosophical literature. See Table 10.2.

How far can or should reduction be pushed? Three different answers to this question have been proposed: antireductionism, radical reductionism,

TABLE 10.2

The various aspects of theory reduction. $\mathcal{T}_1$ = reducing theory, $\mathcal{T}_2$ = reduced theory, D = set of reductive definitions, A = set of additional promises (data or hypotheses)

Aspect	*Full or strong reduction*	*Partial or weak reduction*
Logical	$\mathcal{T}_2$ follows from $\mathcal{T}_1$ plus D.	$\mathcal{T}_2$ follows from $\mathcal{T}_1$ plus D and A.
Semantical	Every predicate in $\mathcal{T}_2$ is in $\mathcal{T}_1$, possibly via D. (So all the peculiar predicates of $\mathcal{T}_2$ are eliminated.)	Some predicates in $\mathcal{T}_2$ are not in $\mathcal{T}_1$ but are built in terms of predicates in $\mathcal{T}_1$, D, and A.
Ontological	The reference class of $\mathcal{T}_2$ is included in that of $\mathcal{T}_1$.	Some referents of $\mathcal{T}_2$ are emergent with respect to those of $\mathcal{T}_1$.
Epistemological	$\mathcal{T}_1$ helps explain the facts accounted for by $\mathcal{T}_2$.	$\mathcal{T}_1$ helps explain the facts accounted for by $\mathcal{T}_2$, which in turn explains emergents w.r.t. $\mathcal{T}_1$.
Methodological	$\mathcal{T}_2$ is a motivation and touchstone for $\mathcal{T}_1$. $\mathcal{T}_1$ may force some changes in $\mathcal{T}_2$.	$\mathcal{T}_1$ is a tool for building $\mathcal{T}_2$. Confirmation of $\mathcal{T}_2$ reinforces $\mathcal{T}_1$, but refutation of $\mathcal{T}_2$ may be blamed on A or D.
Pragmatical	Some computations are simpler in $\mathcal{T}_2$ than in $\mathcal{T}_1$.	Some computations feasible in $\mathcal{T}_2$ are impossible in $\mathcal{T}_1$ (for want of A's).
Historical	Usually $\mathcal{T}_2$ precedes $\mathcal{T}_1$ in time and helps set up the semantic assumptions of $\mathcal{T}_1$.	Usually $\mathcal{T}_1$ precedes $\mathcal{T}_2$ in time and serves as a foil for building $\mathcal{T}_2$.

and moderate reductionism. *Antireductionism* rejects any attempt to understand facts on one level of organization in terms of hypotheses and data concerning some other levels, on the ground that "the whole is more than the sum of its parts", a popular slogan presumably meaning that wholes possess properties not shared by all its components. The ontological counterpart of antireductionism is *holism*, or the view according to which reality is composed of wholes whose properties are independent of those of their components, which are subordinated to the totalities. The antireductionist strategy is to concentrate on wholes in the hope of understanding the nature of their components. (*Examples*: studying whole organisms and whole institutions independently of the study of their components.) Antireductionism, still found in the backwaters of science and the humanities, is refuted every time a chemical process is explained with the help of physical theories, every time a biological function is explained with the help of physics and chemistry, and every time a social process is explained in terms of the needs, beliefs and aspirations of individuals.

Radical reductionism claims that all concepts, hypotheses and theories concerning things on a given level are reducible to those referring to things belonging to some other levels. The ontological companion of radical reductionism is *physicalism* (vulgar materialism), according to which every thing is a physical entity, and the differences we draw between the physical, the chemical, the biological, and the social, are merely differences in complexity. The radical reductionist strategy is to concentrate on the components of a system in the hope of understanding the latter. (*Examples*: studying cells before whole organisms, and individuals before social systems.) Although in the vast majority of cases reduction is partial rather than full, radical reductionism is extremely popular among natural scientists.

Radical reduction has failed even in physics. In fact physicists currently admit that there are at least three fundamental distinct theories, none of which is reducible to the other: quantum mechanics, quantum electrodynamics, and the relativistic theory of gravitation. (The status of chromodynamics is still uncertain.) These theories are mutually irreducible because they refer to things of radically different kinds: particles, electromagnetic fields, and gravitational fields. (They can of course be mutually related but not reduced to one another.) Classical mechanics has not yet been successfully reduced to quantum mechanics: it is not known which are the subsidiary hypotheses to be adjoined to quantum mechanics in order to obtain the full theory of the motion of extended bodies, i.e.

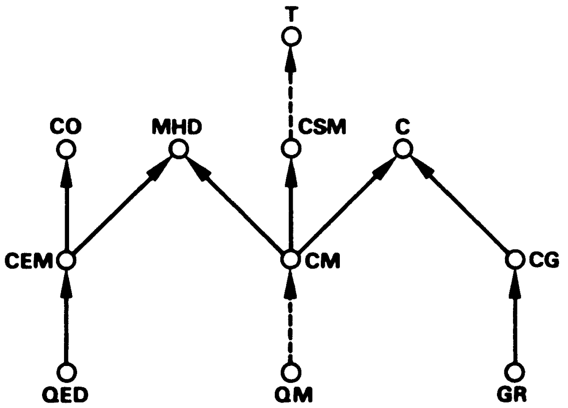


Fig. 10.2. Three basic physical theories of the day: quantum electrodynamics (QED), quantum mechanics (QM), and general relativity or the theory of gravitation (GR). Arrows designate reduction, still incomplete in the case of dashed lines. Classical optics (CO) reduces to classical electromagnetism (CEM), which in turn reduces to quantum electrodynamics (QED). As for QM, one hopes it will be shown to entail classical mechanics (CM), which in turn yields classical statistical mechanics (CSM), which, suitably enriched, should eventually yield thermodynamics (T). Relativistic theory of gravitation (GR) entails the classical theory of gravitation (CG). The union of CEM and CM entails magnetohydrodynamics (MHD), and the union of CM and CG entails celestial mechanics (C). All these reductions are partial. From Bunge (1977b).

continuum mechanics. On the other hand, for strong electromagnetic fields quantum electrodynamics goes over into classical electrodynamics. Likewise, for weak gravitational fields the relativistic theory of gravitation reduces to the classical theory of gravitation. See Figure 10.2. Most of the other reductions cited in the scientific and philosophical literature are instances of wishful thinking. (See Bunge (1973a) for details on reduction relations in physics.) The positivist dream of building a unified science by successive microreductions (Neurath, 1938; Oppenheim and Putnam, 1958; Causey, 1977) has turned to be just that: a dream not even fulfilled in physics. But at least it has been an inspiring dream unlike the antireductionist nightmare. Besides, the unity of science and, indeed, of all genuine knowledge, is fact not fancy: see Ch. 14, Section 3.

Finally, *moderate reductionism* is the strategy of reducing whatever can be reduced (fully or partially) without ignoring variety and emergence—nay, aiming at accounting for them. The ontological counterpart of moderate reductionism is *emergentism* (see Bunge, 1981a), according to which wholes have properties not shared by their components but which, far from being self-existent, result from the latter. The moderate reductionist strategy is to study the whole as well as its parts, in the hope

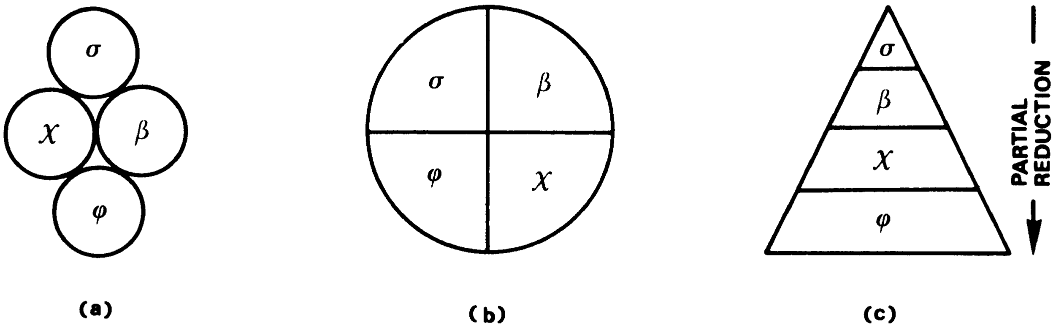

Fig. 10.3. The world and its knowledge. φ = Physics, χ = Chemistry, β = Biology, σ = Social Science. (*a*) Antireductionism: unrelated compartments. (*b*) Radical reductionism: different sectors of a single whole. (*c*) Moderate reductionism: each level higher than the physical one is rooted to the previous ones.

that each kind of research will supplement and spur the other. (*Examples*: studying both individual neurons and neuronal systems, persons and social systems.) Properly analyzed, the most important cases of reduction have been instances of partial reduction. Such successes have refuted both antireductionism and radical reductionism.

Contrary to antireductionism, the various fields of research are becoming more and more integrated, not only by the use of a common methodology underlying the diversity in techniques, but also by relations of (partial) reduction as well as by mergers. And, contrary to radical reductionism, an increasing number of research fields are revealing that the world, though one, has a marvellous variety (accounted for by an increasing number of theories) and a level structure (somehow mirrored in the hierarchy of the sciences). See Figure 10.3. In sum, moderate reductionism is a progressive and realistic strategy, whereas antireductionism is regressive, and radical reductionism utopian.

3.2. *Integration*

Things cannot always be explained by microreduction: quite often they can be explained only by placing them in a wider context. See Figure 10.4. In turn the consideration of such a wider context requires bringing together or consolidating a number of scraps of information and conjecture dispersed among several fields of inquiry. Occasionally such an operation of integration or synthesis brings about the merger of theories and even entire disciplines.

For example, one does not explain the meaning of a word by analyzing it

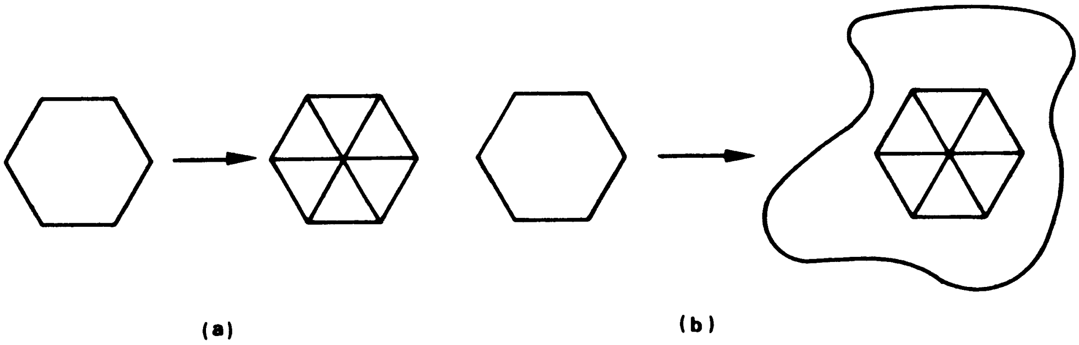

Fig. 10.4. (*a*) Analysis through reduction. (*b*) Analysis through integration.

into its component letters, or even phonemes, but by relating it to other words. The life history of an individual organism is explained not only in terms of genetics and physiology but also in ecological terms. In particular, the behavior of a psychologist could not be explained by only looking into his brain or by watching some indicators of his brain activity: one must also study the systems of which he is a component, such as his family, his laboratory, his scientific community, and even his entire culture. A last example: classical microeconomics, a typically reductionistic enterprise, has failed to explain the behavior of households and enterprises for disregarding their wider social context. One cannot account for the actions of a thing apart from the state of the system it is embedded in. Thus one could not possibly understand why the manager of a firm decides to manufacture product X unless there is a market for X (or one can be created by advertising). And this depends not only on individual needs and wants but also on macroeconomic circumstances and, indeed, on a number of political and cultural variables as well. In sum, what we need is the integration of microeconomics and macroeconomics, not the reduction of one to the other. (More on this in Vol. 6.)

The integration of approaches, data, hypotheses, theories, and even entire fields of research is needed not only to account for things that interact strongly with their environment. Epistemic integration is needed everywhere because there are no perfectly isolated things, because every property is related to other properties, and because every thing is a system or a component of some system (Vol. 4). Thus, just as the variety of reality requires a multitude of disciplines, so the integration of the latter is necessitated by the unity of reality. See Figure 10.3.

Because the unification of knowledge via integration has been sadly neglected by philosophers, particularly those of reductionist leanings, it will be convenient to draw a somewhat long list of successful integrations in science. (*a*) Until recently physicists tried to build one theory per particle species. The large number of particle species, as well as the many relations among them, has necessitated an integrative approach based on the conjecture that each member of a particle species is a state of an underlying particle, much as the electron and the positron are two states of a single particle. (*b*) The relativistic theory of gravitation is not self-contained: in order to solve its equations one must borrow the so-called constitutive relations (determining the so-called matter tensor) from other fields of inquiry. (*c*) The solid state physicist does not start from scratch but makes use of a number of theories, from quantum mechanics to statistical mechanics. (*d*) The theoretical chemist can rarely afford to make *ab initio* calculations: usually he uses both classical chemistry (in particular chemical kinetics) and quantum mechanics, and sometimes even classical particle mechanics. (*e*) Until recently the formation of mountains, earthquakes and vulcanism were treated as separate processes and even by different disciplines. Ever since the plate tectonics revolution, geology treats them as different aspects of the same process. (*f*) Contemporary theoretical meteorology is the outcome of the synthesis of two formerly disjoint theories, namely fluid dynamics and thermodynamics. (The former, which dealt with ideal viscosity-free fluids, had to be rendered more realistic before it could be applied to the atmosphere and the ocean.) (*g*) The stellar atmospheres (in particular the solar corona) could not be studied properly until fluid dynamics and magnetism were fused into magnetohydrodynamics. (*h*) Physiological psychology (or neuropsychology) is a merger of neurophysiology and psychology. Its aim "is not to replace one science by another, but to close the gap between the two sciences—to proclaim their unity, in principle" (Bindra, 1976, p. 19). This unified approach should overcome the one-sidedness of the earlier, reductionist schools, which had attempted to explain behavior, affect, perception, and cognition, in terms of either external stimulation (behaviorism), affect (psychoanalysis), cognition (cognitivism), or some other alleged first mover.

We are now ready to analyze the merger or amalgamation of two or more theories (hypothetico-deductive systems). During the discussion it will be convenient to bear in mind such paragons of theory merger as analytic geometry (the synthesis of synthetic geometry and algebra), celestial mechanics (the union of mechanics and the theory of gravitation), electromagnetic theory (the merger of the theories of electricity and magnetism), thermomechanics (the synthesis of continuum mechanics and thermodynamics), the synthetic theory of evolution (the merger of Darwin's classical theory of evolution and genetics), and evolutionary ecology (the currently attempted merger of population genetics and population ecology).

The simplest case of theory merger is the union of two or more theories (or rather their sets of formulas). Obviously, not every such union is "meaningful". The precursor theories must share referents and therefore also some specific concepts (variables, functions). This is the case with mechanics and the theory of gravitation, the precursors of celestial mechanics. Here the force that occurs in Newton's laws of motion is calculated in the theory of gravitation. (The latter theory did not exist in Newton's time: it was a 19th century creation.) Likewise, the synthetic theory of evolution is the union of Darwin's theory with genetics. However, there are not many more examples of theory union.

In the vast majority of cases the precursor or founding theories have to be supplemented with formulas connecting concepts of the two theories and thus acting as a glue between them. For example, an algebra with a $+$ operation and another with a $\times$ operation can be amalgamated only if both operations are defined on the same set (i.e. if the referents are the same) and if glue formulas such as "$(x + y) \times z = x \times z + y \times z$" are added. To take an even more telling example, and the pioneer in theory merger: Descartes built analytic geometry by assigning every point in Euclidean n-space a unique n-tuple of real numbers and conversely (i.e. by postulating a bijection between E^n and $\mathbb{R}^n$), thus mapping every geometric figure onto a set of n-tuples of real numbers. The theories of electricity and magnetism could not have been synthesized into the electromagnetic theory without further ado: Faraday's law of induction and Maxwell's conjecture of displacement currents had to be added.

In general we shall say that $\mathcal{T}$ is a *merger* of $\mathcal{T}_1$ and $\mathcal{T}_2$ if, and only if,

(i) $\mathcal{T}_1$ and $\mathcal{T}_2$ share some referents and some concepts (e.g. functions);

(ii) there is a (possibly empty) set G of (glue) formulas relating some concepts of $\mathcal{T}_1$ to concepts of $\mathcal{T}_2$, and

(iii) the (glue) formulas in G are sufficiently confirmed.

Condition (i) excludes theories that have nothing to do with one another. (*Caution*: the sharing of spatial or time coordinates does not count, for they are universal features.) Condition (ii) makes room for theory union as the particular case when G is empty. And condition (iii) is added because, in principle, there are infinitely many possible glue formulas. Only those matching the available data will hold the original theories effectively together. By the way, note the methodological difference between glue formulas and the reductive (or bridge) identities of the previous sections: whereas the latter are definitions, the former are postulates.

To sum up, integration is at least as frequent as reduction and just as important a factor of the unity of knowledge. See Figure 10.4. Integration and reduction accompany specialization and make up for its narrowness and centrifugal tendency. Integration is particularly conspicuous in the study of macrosystems, natural or social, because of their multiple aspects and the several levels of organization they cross. Despite their enormous variety, science and technology are one in multiple ways: (*a*) all the chapters of science and technology share a general outlook or philosophical background; (*b*) all the sciences and technologies share logic and mathematics; (*c*) all the sciences and technologies share the scientific method; (*d*) every science and every technology deals with one part or aspect of reality (the only world there is); (*e*) every science and every technology is closely related to at least one other science or technology, so that the totality of sciences and technologies forms a system; (*f*) all of the sciences share the goal of getting to know laws, systematizing them into theories, and using them for cognitive or practical purposes; (*g*) all of the technologies share the goal of using knowledge in the design of artifacts. Therefore there is no need to try and reduce all sciences to physics (as physicalists have demanded) or to psychology (as suggested by phenomenalists), or to merge all theories into a single all-encompassing theory. Science and technology are already one in spite of the inevitable failure of such quixotic attempts. What has to be done is to tighten the system, by reducing the reducible and integrating the integrable.

4. FORECASTING

4.1 *From Expectancy to Forecast*

All higher vertebrates seem capable of expectancy, i.e. of adopting the attitude of anticipating impending events. The animal that expects something to happen may be curious, elated, or frightened, but not indifferent to the future: he has a definite "set" (*Einstellung*). He may expect something to happen or he may have a definite expectation on the strength of a learned association. If he has learned to expect event *B* to follow event *A*, either regularly or with some frequency, a characteristic wave (the *E* wave) will appear in his forebrain (Grey Walter *et al.*, 1964).

The predictive abilities of some animals are quite remarkable. If I throw a stick for my retriever and continue to walk, the animal will meet me further on along the pathway without retracing his steps: somehow he has "computed" my path and adjusted his own to it. When we perceive a regular wave motion we detect its periodicity and anticipate the motion. Similarly we can often complete sentences that other people start and fragments of melodies we have caught. We do all this without using any explicit predicting techniques. Expectancy, and a modicum of forecasting ability, seem to be in the survival kit of all higher vertebrates. *Praemonitus, praemunitus* (Forewarned, forearmed).

Presumably, the more strongly an event is correlated with a previous event, the easier it is to learn that the latter is a predictor of the former. However, such objective correlation is not sufficient for learning about it. Contrary to what one might expect intuitively, experiment shows that animals learn to associate an event *A* to a latter and correlated event *B* only if they are *unable* to predict *B* from *A*: the more surprising an event the better we learn to associate it with its predictor (Rescorla and Wagner, 1972). The reason could be that the more surprising events are more intensively "processed" in the brain.

Although the neurophysiology and psychology of expectancy and forecast have made a good start, we still have to conjecture the way we learn predictive relations. An attractive conjecture is the following (Bindra, 1976). Suppose an animal learns that event *A* is often followed by event *B*, and so learns to predict *B* from *A*. What happens in its brain is that the events as well as their relation are represented by activities of neuronal systems which Bindra calls 'contingency organizations'. If the contingency organization representing event *A* is activated in the animal that has learned the *A*–*B* connection, then it stimulates or primes the perceptual representation of *B* even before *B* happens. That is, the psychon of the *A*–*B* connection causes an advance excitation of the psychon of the predicted event *B*, or at least predisposes the latter to activation (by lowering its excitation threshold). The actual perception of *B* is therefore facilitated by the predictor event. In other words, the animal that knows that *A* is followed by *B* expects *B* upon perceiving *A* (or imagines *B* upon imagining *A*) and is thus better prepared to perceive *B* and act in consequence. See Figure 10.5.

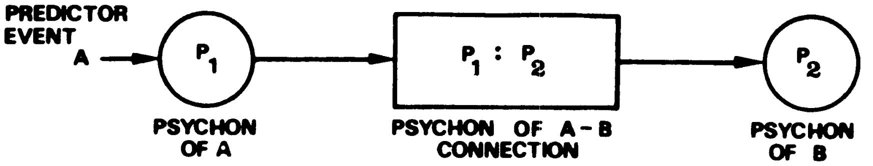

Fig. 10.5. The neurophysiology of prediction. Predictor even A activates psychon p_1, which acts on contingency organization $p_1 : p_2$, which in turn controls the excitation level of p_2, the psychon of the predicted event B. From Bindra (1976, p. 132).

The fact that we have definite neural mechanisms for prediction does not mean that all our forecasts are correct. Many things may go wrong with our predictive mechanisms. We may have learned the incorrect pairings, e.g. to expect a catastrophe every time our path crosses a black cat. Or we may have learned the correct pairings but the predictive mechanism was inhibited, or was interfered with by some other psychon. Or, and this is the most common case, we may have failed to learn any predictive pairings at all—and yet we may be foolish or hard pressed enough to make predictions. This explains the well-known fact that most intuitive forecasts, and even a high fraction of expert forecasts (in medicine, business, and politics) are erroneous.

We hardly needed psychological research to tell us this. What psychologists can do is to try and find out what prediction strategies people use and how they perform. Kahneman and Tversky (1973) studied the problem and found that their subjects, far from using all the evidence at their disposal, selected evidence of one kind only and, moreover, ignored evidence that, if attended to, would have elicited a different judgment. (Specifically, the subjects were asked to predict the area of specialization that a certain individual, whose personality sketch had been drawn on the basis of projective techniques, and which was known to them, was likely to choose. The subjects relied only on this personality sketch, even though knowing that projective techniques are unreliable; and they predicted, e.g. that a given subject would choose computer science, even though knowing that the fraction of the student population that chooses computer science is small.)

From a logical point of view forecasts are special cases of description. They describe events or processes that are not yet or may never be, and therefore are conjectural rather than known with certainty. Indeed a description may refer to past, present, or future events. A description of future events is called a *prediction*, one of past events a *postdiction*. Predictions, postdictions and descriptions of current events are all nonexplanatory accounts. True, some predictions and postdictions are more chancy than some descriptions, but this is not always the case. Thus, a prediction of planetary movements is more accurate than either a postdiction or a prediction of human behavior. In sum, prediction and description do not differ in logic and they need not differ in truth value. The difference between them is methodological: the ultimate check of factual hypotheses and theories consists in checking the predictions or postdictions made with their help. But checking belongs in Ch. 11.

Forecasts can be classed into intuitive and rational. An *intuitive forecast* uses only tacit premises or perhaps none; a *rational forecast* employs only explicit premises: it is the logical consequence of a deductive argument from hypotheses (e.g. law statements) and data. Intuitive forecasts are more or less imaginative inventions, and often just wishful or dreadful thinking. Examples of this kind of forecast are the long term weather forecasts that the *Farmer's Almanac* has been publishing every year since 1792 with the help of a "secret formula". Though widely believed, such forecasts have been shown to be not much better than those obtained by flipping a coin (Walsh and Allen, 1981). Because the premises of an intuitive forecast are hidden or nonexistent, we cannot learn anything when watching its performance. On the other hand the success or failure of a rational forecast is likely to teach us something about the relevance, accuracy, and sufficiency of the premises employed in formulating it.

Intuitive forecasts on a grand scale are called *prophecies*. In the past prophesying was an occupation of shamans, priests, astrologers, soothsayers, and politicians. It has now become an industry that may be called *prophetic futurology* (or *pop forecasting*), to distinguish it from serious futurology, which is concerned with planning on a grand scale, i.e. with redesigning society. Unlike the prophets of the Old Testament, who were interested mainly in domestic events and knew no electronic gadgets, the high priests of modern prophecy deal with world events and extrapolate from modern technology. For instance, they prophesy that before long everyone will be assured of a decent income and will enjoy programmed dreams and individual flying platforms (Herman Kahn). They tell us matter-of-factly that the 21st century will be run by computers that (who?) will dispense justice and keep us out of mischief, will solve all intellectual and practical problems, will keep track of all we do and fill in for us when we fail to do our duty, on top of which they will design and construct even more intelligent and efficient machines. Sadly, none of the modern prophets were able to forecast any of the major events of the recent past, such as the oil crisis, stagflation, the Green Revolution, the Islamic revival, the defeat of the U.S.A. in Vietnam, the Sino–American alliance, the ousting of Somoza, the return of Juan Perón and Indira Gandhi to power, the Falklands war, or the decline in the pace of technological innovation.

Modern prophecies, just like those of Ezequiel, Daniel, and Isaiah, are of the form *B will happen at time C*—e.g. money will have disappeared by the year 2000. That is, they are unconditional statements, unlike the conditionals of scientific prediction, which are of the form "If *A* happens (or continues to be the case), then *B* will (or may) be the case at time *C*". But, unlike the prophets of old, the modern prophets make wild extrapolations from current technological trends and they disregard the social constraints: they take it for granted that whatever the technologist may come up with will instantly be adopted across the frontiers. Moreover, they assume wrongly that they have sufficient knowledge of the present, which is never the case if only because they are usually specialists with a one-sided vision of the world.

Some of the pitfalls of intuitive forecasting can be avoided by pooling and sifting the opinions and speculations of a number of experts in a given area and determining the points of consensus. This is what the Delphi "method" boils down to—although it was initially advertised as "a tested technique of long-range forecasting" (Helmer, 1966). It is now regarded as merely a procedure for gathering "soft" (i.e. subjective and unchecked) data in the social technologies (Linstone and Turoff, 1975). It lacks theoretical justification and it is yet to be seen whether it is successful.

Rational forecasts, like descriptions, can be extratheoretical or theoretical. Most of the rational forecasts made in medicine, education, economics, and politics, are extratheoretical: they employ predictors, not theories. For example, the general practitioner prognosticates on the basis of vital indicators, the teacher and the businessman on the strength of past performance, and the economist and politologist extrapolate present trends. Any sign or indicator used to make forecasts is called a *predictor*. For example, we employ the results of entrance examinations as predictors of scholastic performance (even though we ought to know that they are poor predictors), on the assumption that the student will continue to behave as in the past. This is the way high school students are admitted to college, graduates hired as professors, employees promoted to management, and managers to directors. The hypothesis that anyone who is good at any given level must be good at the next higher level works much better than the superficial impressions one may get from an interview, and better than recommendations. However, it is not quite correct, because the abilities required in each case are different. Oversight of this well known fact leads to adopting the famous Peter Principle: "Everyone gets promoted to his own level of incompetence".

(One way of elucidating the notion of a predictor is as follows. Suppose we know two kinds of events, E_1 and E_2, and know also that they are related. This relation can be either constant (e.g. causal) or probabilistic. I.e., either some event of kind E_2 happens every time an event of type E_1 occurs, or there is a definite probability of an E_2 happening every time an E_1 occurs. In the first case any functional relation between some property of E_1's and some property of E_2's can be used as a predictor of E_2's. In case the relation is stochastic we may take the difference between the conditional probability $Pr(e_2|e_1)$, for e_1 in E_1 and e_2 in E_2, and the absolute probability $Pr(e_1)$, to measure the value of E_1 as a predictor of E_2. More precisely, we may define the *predictive value* of E_1 for E_2 as

$$v(e_1, e_2) = Pr(e_2|e_1) - Pr(e_1) \quad \text{for all } e_1 \in E_1 \text{ and } e_2 \in E_2.$$

This difference is positive only in case e_1 is favourable to the occurrence of e_2; it vanishes if e_1 and e_2 are statistically independent. If the predictive value of E_1 for E_2 is positive, E_1 can be said to be a *predictor* of E_2. From the above we see that a predictor may be a cause, an indicator of a cause, or any event functionally associated with the event of interest.)

All governmental agencies and many private enterprises extrapolate current trends in population, energy consumption, industrial production, use of various items, and so forth. Such extrapolations assume that nothing is done to curb the given tendencies. Such forecasts, which often involve massive use of data and computers, are sometimes called *scenarios*. Scenarios have little cognitive value because they result from mere extrapolation of current trends. But, by the same token, they may have immense practical value in sounding timely alarms and suggesting plans. For example, one of them tells us that, if the world population were to continue growing at its present rate, there would be no standing room left by the end of the next century; another that, if car sales continue at the present rate, every human, including infants, would own a car by the year 2050; still another, that the consumption of hard drugs would exceed that of food.

Because they are absurd, such scenarios suggest that something is wrong with some of our present systems: that they will break down unless we interfere with them. "By so doing one can plan interventions *now* rather than wait, as is usually the case, until the system is in a state of crisis" (Ackoff, 1978, p. 128). For example, all experts in nuclear warfare are agreed on the following: (*a*) in case of a (or rather *the* first and last) nuclear war, all the major towns in the northern hemisphere would be destroyed; (*b*) there is no effective shelter against nuclear blast or even against radioactive fallout; (*c*) as long as there are stockpiles of nuclear warheads it is possible that a nuclear holocaust be started by an irreflexive head of state or even by mistake. Such forecasts should suffice to persuade any rational being that total nuclear disarmament is necessary (though not sufficient) to preserve the human species, at least for a while.

The rate of success of extrapolations of current trends is far superior to that of intuitive forecasts, such as those based on clinical judgement, unstructured interviews, or projective tests. In particular, statistical forecasts, made on the basis of regression equations, work reasonably well at least in the short run, not only in the social sciences, especially in economics, but also in medicine and clinical psychology (Sawyer, 1966; Dawes, 1980). Even the simplest statistical model (linear regression or correlation) does better than the intuitive forecast. Still, statistical predictions (i.e. extrapolations of present tendencies) are far poorer than theoretical predictions, i.e. forecasts with the help of theories. The reason is that, unlike every other kind of forecast, theoretical prediction involves laws (and also rules in the case of social science), not just trends that can change overnight.

Thus a knowledge of statics, and the information that a particular lever is in equilibrium, allow us to predict that, if the weight or the length of one of its arms changes, the lever will become unbalanced. This forecast is qualitative both with regard to the imbalance condition and the time. An instance of a quantitative forecast is this. If the law of growth (or decay) of a certain magnitude (e.g. the number of individuals in a population) is exponential, and one knows or assumes both the initial value of the magnitude and its growth (or decay) rate, then one can forecast with precision the value of that magnitude at any time. One can also make several other predictions, e.g. the precise time at which the given magnitude will have doubled (or halved). To be sure, such a precise forecast may turn out to be false, but this failure will be instructive: it may indicate that some limiting factor (e.g. scarcity of resources, crowding, or competition) is at play. No such lesson can be learned from an intuitive forecast.

The truth of a forecast must be distinguished from its precision, for—as every fortune teller knows—the less definite a forecast the more chances it has of being true. Consider the following forecasts:

(i) Anything may happen.
(ii) Something will turn up to solve the energy crisis.
(iii) Some day man will learn to control society.
(iv) There won't be any fossil fuel left by the year 2100.
(v) The Halley comet will be visible from Earth on April 11, 1986.
(vi) The probability that an atom of species A in state B will emit a photon within time t, is p.

These forecasts are of different degrees of definiteness. The first is the least definite of all; fortunately we may disregard it, for it conflicts with the principle of lawfulness. The second is mere wishful thinking, since very little, aside from rather slow progress on fusion and satellite solar power, is being done to avert the impending catastrophe. The third too is rather indefinite but it is somewhat better grounded than the preceding, because social science is making progress, and planning is gaining world-wide acceptance. Forecast (iv) results from extrapolating current fuel consumption and population trends, so it is both definite and well grounded—though unreliable because those trends may not continue. The last two forecasts are both definite and well grounded. Unlike the preceding ones, they are theoretical predictions. Let us take a closer look at them.

4.2. *Scientific Prediction*

There are only actuals—by definition. But of course possibility is of the very essence of actuality: nothing can be, or cease to be, unless it is really possible to begin with. (For our definition of real possibility in terms of laws see Vol. 3, Ch. 4.) All actuals change and induce change in others. However, as long as such changes do not occur, they are nothing but possibilities. Nothing prevents us from, and everything advises us to, imagining possibles—possible things, states of things, and changes in such states, i.e. events. This is what forecast is all about: imagining possible individuals. Such imagination may be fanciful, as in fiction and prophecy, which are restricted at most by logic; or it may be controlled, as in scientific forecast.

Controlled forecast, as practised in science and technology, is of either of two kinds: *empirical* (though not intuitive) and *theoretical*. The former uses statistical correlations, regression lines, and other statistical tools; on the other hand theoretical forecast involves the knowledge of laws. Evidently, theoretical forecast is in principle superior to empirical forecast, because laws are deeper and firmer than correlations. However, theoretical forecast may score lower than empirical forecast if it relies on incomplete or inaccurate data, as is the case with weather forecasting. Let us catch a glimpse of the latter.

The traditional method of weather forecasting uses empirical generalizations, while the theoretical method employs a sophisticated mathematical model of the atmosphere that combines fluid dynamics with thermodynamics. Use of the former method calls for considerable flair that can be educated. On the other hand, once the theoretical model has been chosen and the data are in, numerical forecasting can be entrusted to a high speed computer (as is done at the U.S. National Meteorological Center and a few other institutions). Unfortunately the meteorological data are not only inaccurate but also incomplete. For one thing they do not include values of the entropy, the energy fluxes, and other functions; for another, they fail to cover vast regions of our planet, such as the oceans and the arctic and equatorial regions. So, even assuming that the theoretical model is correct—a very doubtful assumption, if only because it is a non-probabilistic model—it contains variables that go unmeasured, and others that are measured only in some places and with large errors. As a result, the empirical weather forecasts are still, after four decades of work on theoretical forecasts, more accurate than the theoretical ones.

This *impasse* has led some meteorologists to suggest giving up computer simulations of the atmosphere (Sanders, 1979) or even abandoning the project of theoretical forecast altogether (Ramage, 1976). Yet presumably something can be done about this crisis—e.g. to try more sophisticated models of the atmosphere, and to multiply the number of (automated) meteorological stations. (Incidentally, weathermen are in the habit of speaking of probabilities, e.g. of precipitation. This use of the term 'probability' is incorrect, because neither the empirical regularities nor the theoretical models involved in weather forecasting are probabilistic. When the weatherman learns that in the past p percent of the time the atmosphere looked in such and such a way the next day it rained, he forecasts: "The probability of rain tomorrow is p". Here p is a percentage not a probability. There are no probabilities unless there is randomness: see Bunge, 1981c.)

Empirical (statistical) forecasts are based on unexplained correlations, which are precise measures of the strength of the association between two variables, each of which represents a property of some concrete thing. Thus if we have found that X correlates highly with Y, then every time we find X

we may expect to find Y as well—provided the correlation holds out instead of being spurious as in the famous cases of the correlations between grain crops and sunspots, or between divorces and foxes killed in Finland. For example, for every human population there is a definite correlation between height and weight. This correlation can be used to predict the one from a knowledge of the other in the given population. (But of course it does not apply to a different population or to individuals, who may become leaner or fatter without changing in height.) Once we have obtained a correlation coefficient we can draw a line that allows us to extrapolate into the future—assuming that the correlation will hold out. In particular, we can build autoregressive models centered on autoregressive equations, or finite difference equations for a single variable, e.g. $X_t = a_1 X_{t-1} + a_2 X_{t-2}$, which allows us to forecast the value of X at time t in terms of its values at the earlier times t-1 and t-2. All such models are useful forecasting tools and they abound in the life and social sciences. But it is well understood that they yield soft forecasts far inferior to the ones based on theories.

As we saw in Section 4.1, a theoretical forecast is the conclusion of an argument from two groups of premises: theoretical formulas (in particular law statements) and data. We saw also that the occurrence of the time variable in the premises is sufficient but not necessary to make forecasts. For instance Gibbs' phase "rule" (actually a law statement) states that, for any system in equilibrium, with C independent components, P phases, and F degrees of freedom, $C + 2 = P + F$. Two general predictions follow: (*a*) If either of the three properties of a system in equilibrium changes, the system goes into a nonequilibrium state, and (*b*) if a system is in a nonequilibrium state, it will go over to an equilibrium state if either (or all) of the three properties change in such a way that the phase "rule" is satisfied. These predictions are made on the strength of a law statement that does not contain the time concept, and they require counting but not measuring. An even simpler law statement of the same type is the ecological law that, if there is a relation of mutualism between the members of two species, then if either of them increases in number, the other will increase as well.

Most scientific predictions are forecasts of states, events, or processes of known types. Paragons of accuracy are of course the predictions made with the help of celestial mechanics, quantum mechanics, and quantum electrodynamics. In most cases they forecast not only what will happen (or what cannot possibly happen) but also when the event will happen, or at least the probability that it will happen within the next time unit. (If such probability p is calculated then it can be expected that, on the average, the event concerned will happen pN times out of N occasions.) The standard inference schema of any such forecasts is: *Model of the thing(s) concerned plus data entails prediction*. Since in the cases we have mentioned a general theory is involved, the model is obtained by enriching the former with specific assumptions concerning the composition, structure, and environment of the system of interest. (For the notion of a bound model recall Ch. 9, Section 1.2.)

Some of the most exciting scientific predictions are not of states or events of known kinds but of the very existence of previously unsuspected things. Here is a random sample of the increasing collection of forecasts of this type: Darwin's postdiction of the existence of our hominid ancestors, Maxwell's prediction of electromagnetic waves, Mendeleev's prediction of the existence of the elements scandium, gallium and germanium; Oppenheimer's prediction of neutron stars (pulsars), and the prediction of new, as yet not synthesized molecules, made almost every day by organic chemists. All these predictions and many more were made with the help of scientific systematizations and they were borne out by observation or experiment—nay, they guided the latter. Predictions of the same type, but not yet verified, are those of gravitational waves and of superheavy elements (with nuclei around $Z = 114$).

The most satisfactory theories are those which are at the same time predictive and explanatory. Modern planetary astronomy is of this kind; on the other hand the theory of evolution is far too general to be able to make any quantitative predictions. Ancient planetary astronomy, in particular Ptolemy's, was predictive but not explanatory: it was but a device for computing appearances from appearances. Therefore the ancient skeptics were right in doubting that the sun would "rise" the next day. We can now be certain that it will "rise" because we know the mechanism of the alternation of days and nights, namely the spinning of the Earth. (We may doubt on the other hand whether there will be any life left on earth if the superpowers continue to prepare for the final solution to all our problems.)

How is it possible to predict the existence of unheard-of properties, events, and even things? If every scientific statement were nothing but a datum or an empirical generalization, such predictions would be miraculous. First, because before the actual finding of the predicted object there was nothing to generalize from; second because, on an inductivist philosophy, there is no reason to suppose that properties and things could be necessarily (lawfully) related to one another. On the other hand, on the view that theories are hypothetico-deductive systems, serendipity loses its miraculous quality while keeping its magnificence: if certain assumptions are made, a host of conclusions can be drawn, some of which must be unexpected when only the assumptions are examined. Something similar happened with the predictions made on the basis of classificatory schemata such as the periodic table of the elements and the systematics of elementary particles. In both cases certain pigeonholes appeared empty which arose the curiosity of experimentalists to look for things that could possibly fit into them. These discoveries, then, were not lucky accidents. They only illustrate the power of conceptual systematization (classification and theory) to guide experience and thus enrich it. See Appendix 4 for the notion of predictive power.

According to many thinkers, from Ptolemy and the judges of Galileo to Comte and Lakatos, prediction is the hallmark of science: everything else is unimportant. On the other hand Popper believes explanation to be more valuable than prediction, which he regards as unimportant except for technological purposes. As usual, the truth lies in between: prediction is a mark of science though not its only peculiarity nor characteristic of every bit of it, for none of the extremely general theories can make any prediction unless enriched by subsidiary hypotheses and data. Prediction is valuable in itself because it widens the collection of knowable facts. And it is *a* mark of science because, unless there is some prediction, nothing can be tested, and without testing there is no science. (Pseudoscience, in particular psychoanalysis and parapsychology, makes no precise predictions.)

Can we predict everything? Here again there are three possible answers. Fortune tellers, economic advisors, stock brokers, and some politicians claim that they can predict everything: after all they make a living off prophesying. On the other hand many social scientists and philosophers believe that nothing important can be forecast. As usual, neither the optimists nor the pessimists are right. Predictability is not a property of events but of our cognitive relation with them: we can predict provided we know enough. Moreover, since prediction is performed within a body of knowledge, and every such body is incomplete and inaccurate, not everything can be predicted at a given moment, and if predictable it is predicted with some error. And, granting that we shall never attain perfect knowledge, there will always be unpredictables. But, assuming that future generations will continue to care for scientific research, we can also forecast that knowledge will continue to grow, and thus the number of predictables increase.

Neither the rationalist nor the realist need lose any sleep over unpredictables. What should disturb them is the threat of diminishing research. Still, could we discover any unpredictables, i.e. facts either unknowable or lawless? If unknowable, we need not worry: out of sight, out of mind. If lawless, they would be beyond the reach of science, for lawfulness is a (philosophical) presupposition of scientific research. (This principle is irrefutable: if anyone were to point to a certain fact as lawless, we could ask for some time to investigate it in the hope of discovering its laws.) Two candidates come to mind: time series and the outcomes of research and invention. Let us catch a glimpse of each.

A *time series* is a sequence of data of some kind (e.g. total population, or precipitation) taken at regularly spaced intervals, e.g. years. Whereas some time series are random, others exhibit a pattern. The former are unpredictable unless the underlying mechanism is discovered; the others are predictable within bounds. (The degree of predictability of a time series is measured by the autocorrelation function, whose values are computed from the correlation between observation results separated by two, three, etc., intervals. In a predictable time series the correlation coefficient will, typically, fluctuate at the beginning, settling down to a constant value after a while.) In either case a time series is not a brute fact but a way of displaying a collection of brute facts. Hence it is not an instance of an inherently unpredictable fact.

The case of research and invention is more difficult. We know that problems are in the habit of seeming to pop up unexpectedly, and that hypotheses and ideas for experiments or designs come unanticipated. And we also know that even the most carefully planned research is full of surprises, to the point that the initial problem may be replaced with another, and a new method may be invented to handle it. (It follows that no research plan should be detailed and rigid for, if it were, it would suffocate original research. Only routine research can be planned and forecast in detail.) It would seem, then, that originality is unpredictable.

Still, research leaders do make forecasts concerning the research they are responsible for. They make them on the basis of what is known now, as well as on their knowledge of the available human and material resources. Thus Crick (1966) forecast the synthesis of enzymes and even genes, which were actually performed a few years later; and Watson (1976), in his well-known textbook, lists a number of open problems and notes that many of them will probably be solved within the next decade. So, some forecasts of the outcome of original research *are* made successfully. (And, *pace* Popper, such predictions are not logically impossible, for they do not consist in solving problems but in hazarding that the problems will be solved.) But they are intuitive forecasts, not scientific ones: they extrapolate from current events. (Moreover, they are partly self-fulfilling forecasts, for they incite young researchers to take up certain problems.) A scientific forecast of scientific and technological creations would require an extensive and profound knowledge of the neural springs of creativity and of the social conditions that stimulate and stifle it. And we do not even know whether such knowledge will ever be attained. It would be just as rash to claim that it will be attained, as to state that it is beyond our reach. It is more reasonable and rewarding to work on these problems than trying to predict the outcome of such work.

5. CONCLUDING REMARKS

We all wish to understand what goes on in and around ourselves. Such understanding calls for answering what may be called *the six W's of science and technology: what* (or *how*), *where, when, whence, whither*, and *why*. In other words, understanding is brought about by description, subsumption, explanation, prediction, and retrodiction.

Neither of these epistemic operations is more important than the others. However, most workers specialize in only some of them. Thus collectors, classifiers and field workers are more interested in description than in explanation or prediction; on the other hand theoretical researchers and technologists want to know not only the facts but also why they are so, in particular what makes things tick. Subsumption, explanation, prediction and postdiction are typically theoretical operations, i.e. activities performed with the help of theories—the better the richer and the better organized.

Answering any of the six *W*'s of science and technology is intrinsically valuable: it yields new knowledge. But it may also be instrumentally valuable for allowing us to modify reality to our advantage. Thus if we know how a system works we may be able to keep it in good repair or even to perfect it. Explanation has therefore not only a cognitive but also a practical value. However, explanation is not enough: certain doctrines, such as fatalism, explain everything but, being predictively barren, cannot be put to the test and so cannot be evaluated on empirical grounds. Only theories that help predict or postdict can be contrasted with facts. However, the matter of checking deserves a separate chapter.

CHAPTER 11

PRODUCING EVIDENCE

If we proceed scientifically in any epistemic field, whether scientific, technological, or humanistic, we will try to check our hypotheses and recheck our data. We will not use authority, let alone ignorance, to justify our hypotheses or data. This maxim sounds obvious but it is not. To begin with, the argument from authority is still going strong in many humanistic fields—a remnant of the time when they were not distinguished from ideology. Even in science we cannot dispense with a modicum of authority if we are to use knowledge reaped by others: every time we borrow or quote a result obtained by other workers we hope our source to be "authoritative" (competent and responsible) and put our trust in it. However, this trust is not blind: it is the reasonable belief that the quoted author has proceeded scientifically, and we are ready to give it up the moment it is shown to be incorrect.

As for the argument from ignorance, it is of the form "Since we do not know exactly what X is, or how X came about, we can safely assume that X is Y". Assume, yes; safely, not, for every assumption must be checked. And yet this maxim is sometimes violated in science. Consider the following arguments from ignorance gleaned from the scientific literature. (*a*) "Since we do not know in many cases what the probabilities of the various alternatives are, we may assume that they are equal". (The correct policy is to assume equiprobability as the simplest though not necessarily the most likely hypothesis, and to proceed to check this hypothesis. In the absence of information all hypotheses are equally likely—or unlikely.) (*b*) "If an exception to a given well-tested law statement occurs, it must be for lack of precision in the observation or measurement." (Right policy: Redesign the observation or measurement to see whether the exceptions were genuine or "artifacts", or at least keep those exceptions in mind instead of dismissing them out of hand.) (*c*) "Since we cannot observe a microthing within an arbitrarily small time interval, we can assume that it does not obey any conservation laws between observations". (Wrong: the basic law statements do not say anything about conditions of observation, let alone non-observation. To suspend the laws of physics just because nobody is looking is shear solipsism—or insanity. Yet this is the usual justification for introducing the so-called "virtual" particles and processes. See Bunge, 1970.) (*d*) "Any apparent exception to biological adaptation must be just apparent: if we knew more we would realize that actually it is useful to the individual or the species concerned". (The right hypothesis is that many features of organisms are nonadaptive—e.g. because they are remnants of formerly adaptive traits. The presupposition that every property of an organism is adaptive clashes with the evidence of extinction.)

A characteristic of mathematics, science, technology, and the modern humanities, is that everything in them is checkable: every datum, theory, method, artifact, or plan of action is supposed to be able to pass some test or other, if possible multiple tests. To be sure testability, though necessary to attribute truth or efficiency, is insufficient to decide that an item of knowledge is scientific or technological. Thus astrology, though refuted long ago, never belonged to science; and alchemy, though shown to be both false and ineffective, was never part of technology. In addition to the possibility of testing we need actual testing and we cherish positive test results no less than negative ones. In particular we delight in learning that a theory has been confirmed or a machine actually does what it was designed to do.

We are interested in tests of two kinds: tests for truth and tests for efficiency. They concern objects of different kinds: the bearers of truth are propositions (or the underlying thoughts), and those of efficiency are actions and artifacts (or the underlying proposals, plans, designs, instructions, or norms). Thus whereas data and hypotheses can be true to some extent, norms and computer programs can only be effective to some extent. Truth guides the search for efficiency, and efficiency poses the problem of its explanation, but they are different categories. So much so that truth is often useless, and efficiency is sometimes based on untruth. Thus many true scientific hypotheses have no practical application, whereas some worthless products are commercially successful because of deceitful advertising.

Testability and truth, which are only accessory in the case of prescientific ideologies and public affairs, are central to science, technology, and the humanities. To be sure, doing research in either of these fields is investigating problems with the aim of solving them. But a problem is considered to be solved only if the proposed solution passes checks for truth (in the case of cognitive problems) or efficiency (in the case of practical problems). Therefore it is not true that the success of the scientific enterprise may be gauged by its ability to solve problems regardless of matters of testability and truth (as Laudan (1977) claims). A thoroughly untestable solution is not scientific or technological, and an untested one can be assigned neither a truth value nor an efficiency value.

1. FROM SELF-EVIDENCE TO EVIDENCE

1.1. *Self-evidence*

We are all more or less gullible in some department or other. In some cases we regard our beliefs as self-evident, in others we rely on authority, and in still others we refuse to admit unfavorable evidence. Let us make a quick study of these three cases.

Intuitionist philosophers of all hues agree that there are certain obvious or self-evident truths, i.e. propositions the truth of which is recognized intuitively without any tests, i.e. without evidence, and which serve as a standard relative to which all other propositions are evaluated. Husserl went to the extreme of claiming that some people are endowed with a vision of essences (*Wesensschau*) allowing them to grasp the essence of any object without having to waste their time experimenting or theorizing. But of course the history of mankind is littered with the corpses of supposedly self-evident truths, which are just received opinions and often blatantly false superstitions. What is obvious to the layman may be puzzling to the expert, and conversely. Besides, specialists do not behave homogeneously: what is surprising to one may be self-evident to another. But, if competent and responsible, they will not follow blindly their gut feelings but will test them.

Faith in intuition is not restricted to intuitionist philosophers. In all societies most laymen conform to the judgment, prognoses and decisions of experts, be they plumbers or electricians, physicians or economists, shamans or statesmen. We usually take their word although their judgment is more often intuitive rather than scientific—and often wrong to boot. In particular clinicians are known to propose diagnoses in a hurry and to fail in a high percentage of cases, and economists are prone to make recommendations on the strength of theories which, in the best of cases, have not been tested.

Blind faith, i.e. trust in ideas or procedures that have not passed sufficient tests, is not limited to the professions. Many hypotheses in social science have never been checked or, when tested, have turned out to be false—notwithstanding which they are often kept with ideological zeal. Here is a random sample of such views. (*a*) According to Marxism, the modern state is nothing but the supermanager of capitalism; in particular it always protects the monopolies and takes upon itself to run the low return and losing sectors of the economy. The profitability of the French and Canadian state corporations has conclusively refuted that thesis (Niosi, 1981). (*b*) According to neoclassical microeconomics prices are fixed by the play of offer and demand: the price of a good or service is that for which the offer equals the demand. Actually the big corporations fix prices without regard to demand (Galbraith, 1967; Silberston, 1970). (*c*) According to Durkheim, the rate of crime in any stable society is constant over time, so there is nothing one can do about it. The data, at least for California between 1851 and 1970, are inconsistent with this hypothesis and show that the crime rate fluctuates rather wildly (Berk *et al.*, 1981).

We all tend to protect our most cherished beliefs, particularly when we have invested much time and effort acquiring them—as is the case with theologians, political ideologists, and economists. Thus if someone believes that prayer (or vitamin C) will protect him from the common cold, he will pray (or take vitamin C) regularly; should he catch a cold in spite of this, he will probably double the dose rather than question his belief. Failure to admit negative evidence is a very natural disposition: skepticism is learned only the hard way. Jevons (1877, p. 402) remarked long ago that "It is difficult to find persons who can with perfect fairness register facts for or against their own peculiar view". Contemporary psychologists have confirmed this "law of the disregard of negative information". Thus psycholinguistic experiments have shown that "Most people prefer to accentuate the positive" (Miller, 1967, p. 168). Even if they get to know the worth of their false beliefs and wrong actions, most people make hardly any use of such feedback. (See Festinger *et al.* (1956), Wason and Johnson-Laird, (1972), and Shweder (1980), for some experimental material on the tenacity of belief in the face of contrary evidence.)

The most common attitude in the face of unfavorable evidence is then one of disbelief or indifference, or at most doubt. This attitude prevails not only in ordinary life but also in science: "facts that fit into a preconceived hypothesis attract attention, are singled out, and are remembered; facts that are contrary to it are disregarded, treated as 'exceptions', and forgotten" (Luria, 1975, p. 339). There are several possible and mutually compatible reasons for such conservatism. One is that negative evidence is seen as failure or even as threat or humiliation: discarding it or "rationalizing" it is then regarded—particularly in success-oriented communities—as necessary for the preservation of self-esteem. Another reason is sheer intellectual laziness: it may be too hard to modify one's body of beliefs to accommodate the fresh evidence. A third is social (economic, political, or cultural) conservatism tied to vested interests (economic, political, or cultural)—as is the case with the persistence of moth eaten beliefs such as economic laissez-fairism, political centralism, and religious fundamentalism.

However, conservatism is not all that bad: it all depends on what it attempts to keep. Besides, cognitive conservatism is deeply ingrained in our brain and, to a point, it is methodologically justifiable. Let me explain. First of all, psychologists know that—unlike computers—we do not accept new information the moment we acquire it, but screen it for compatibility with our belief system (Rokeach, 1960). If the new information is consistent with our belief system or irrelevant to it, we tend to accept it without much scrutiny; otherwise we tend to alter it to adapt to our fundamental beliefs—or we just reject it. In short, we evaluate new information as it comes in, attributing far more value to favorable than to unfavorable data.

Such epistemic conservatism is double-edged. On the one hand it blinds us to new unsettling information. On the other it spares us countless mistakes. After all, the data themselves may be incorrect: we did not look or measure carefully, the entire experimental set-up was vitiated by some systematic error (e.g. a leak), or we were hallucinating. So, it is methodologically sound to question and even discard data incompatible with a body of knowledge—provided the latter has been well tested. It is not that we must prevent ugly facts from spoiling our beautiful theories: we must take care not to accept all data at face value, and we cannot assign truth values except in some body of knowledge or other. (Imagine trying to evaluate a report on the spin of gluons without having the slightest clue as to the meaning of "spin" or "gluon".)

Although we are all natural epistemic conservatives, we can learn to check ideas and things, and to modify them or give them up if they fail utterly. Such learning is part of the training of every craftsman, manager, technologist, scientist, and modern humanist. Indeed all the sciences, formal or factual, basic or applied, as well as the crafts and technologies, and the modern humanities, are supposed to abide by the following *testability principle*:

RULE 11.1. Every datum, hypothesis, technique, plan, and artifact must be checked for adequacy (truth or efficiency).

In other words, no matter how a bit of knowledge has been acquired, how a design has been conceived, or how an artifact has been manufactured, they should pass certain tests before being accepted. (Reichenbach (1938) emphasized the difference between the "context of discovery" and the "context of justification". There was nothing wrong with this; his mistake was to believe that it was possible to construct an a priori logic of discovery of generalizations from observations, i.e. an inductive logic.) Whereas we should be permissive with regard to discovery and invention—within the bounds set by the public interest—there is little play when it comes to evaluating them. The checking must be rigorous, for we want truth or efficiency, as the case may be, and neither can be ascertained without tests.

This does not entail that, unlike checking, discovering and inventing are utterly lawless and irrational and therefore beyond the scope of scientific research. The history of science, technology and the humanities teaches us that new findings do not pop up out of the blue: that they answer questions posed before against a certain epistemic background, that they are acquired with the help of means evolved before, and that they lead rather naturally to new developments—provided no social hurdles are in the way. Besides, like all other cognitive processes, discovery and invention can be studied both as brain processes and as social processes. Uncovering their mechanisms and those of their neural and social inhibitions should help us discover and invent, or at least prevent us from interfering destructively with them.

To return to the testability principle (Rule 11.1). To be sure, it would be impossible for us to test every proposition, proposal, and artifact that comes our way: the life and resources of an individual are too short for that. Therefore checking is a social endeavor: we submit our findings to the examination of our peers, and trust most of the knowledge we borrow from fellow workers. But this trust is neither blind nor unshakeable: we trust only the information that has been screened, and we do so only provisionally, i.e. until shown wrong. In other words we adopt the *fallibilist* principle:

RULE 11.2. Regard every cognitive item—be it datum or hypothesis, technique or plan—as subject to revision, every check as recheckable, and every artifact as imperfect.

However, there are degrees of adequacy, hence of inadequacy: some propositions are truer than others, some methods more powerful or accurate than others, some plans more effective than others, some artifacts more suitable than others, and some checks more rigorous than others. Consequently radical skepticism—according to which everything is equally worthless—is as false as it is paralyzing. Only moderate (or methodological) skepticism may help us advance from one inadequate proposition to a less inadequate one, from one ineffective proposal to a less ineffective one, from one unsuitable artifact to a less unsuitable one. Such moderation is controlled by the *meliorist* principle:

AXIOM 11.1. Every cognitive item, every proposal, and every artifact worth being improved on can be perfected.

Of course there is no way of proving this optimistic principle, and this is why, if accepted, it must be adopted as a postulate. All we can affirm with confidence is that so far it has been confirmed—a case of self-fulfilling prophecy. However, the principle has its built-in limitation, namely the proviso that the item to be improved be worth being improved. There are two reasons for this proviso. One is that some items had better been dropped altogether—e.g. torture instruments, cigarette lighters, and leather covers for moustaches. The other is that even serviceable ideas, procedures and artifacts reach a point where any further investments in their improvement would by far outweight the returns on them.

To sum up, self-evidence is illusory, authority can (and must) be challenged, and negative evidence, though we naturally dislike it, lurks behind everything. Hence we must be fallibilists—but, at the same time, meliorists. Our "worlds" of knowledge, plans, and rational action are very far from being the best of all possible worlds, but they are not the worst either and, what is better, they are perfectible.

1.2. *Evidence*

If self-evidence is no evidence, what is? A theoretical consideration can be; also an empirical datum, although not all data qualify as evidence. We shall deal with conceptual evidence in the next chapter, Section 3.1. Suffice it to say here that every well-confirmed theory is evidence for any other theories presupposing the given theory—and vice versa. As for the condition a datum must satisfy to rate as evidence, it boils down to relevance. Let us elucidate these concepts.

A *datum* is a particular piece of information of either of the forms "Thing x is in state (or goes through process) y", and "There are things of kind (or possessing property) *K*". ("Thing *x* has property *P*" is a particular case of the former, since a state is a list of properties.) An *empirical datum* is a datum acquired with the help of empirical operations, such as observation, measurement, experiment, action, or a combination thereof. And a *genuine empirical datum* is an empirical datum obtained with the help of operations that are accessible to public scrutiny. This excludes revelation, hunch, and authority.

Not all data constitute evidence for or against an epistemic item, such as a hypothesis, or a value judgment concerning the efficiency of a plan or the performance of a machine. Only relevant data may constitute evidence. An empirical datum may be said to be *relevant* to an epistemic or an evaluational item only if it refers to the latter. If preferred, a datum is relevant to a proposition if both share at least one predicate. For example, information about the performance and price of a machine are relevant to any statement about the profitability of the machine. On the other hand price and performance are mutually irrelevant even though both refer to the same machine, for a machine may be expensive yet perform poorly, or inexpensive and perform satisfactorily. In other words, there are neither laws nor rules that relate price to performance in a regular way: this is why price and performance are mutually irrelevant. (They may be statistically correlated, though.) On the other hand data about crowding are relevant to hypotheses about social cohesion, because the latter happens to depend upon the former.

Relevance and possible lawful relatedness are not enough for a datum to constitute evidence for or against a proposition or a proposal. In addition, every datum must be interpreted as possible evidence. Such interpretation is built into the very construction of measuring instruments or it is explicitly laid out in their operating manuals on the basis of knowledge about their design and operation. Thus we have learned to read time from a watch, and energy from an electric meter. But in most cases data come uninterpreted: we do not know what they "mean" unless we are able to interpret them in the light of some body of knowledge, preferably a theory. For example, the lay may interpret reports on experiences of dying as evidence for life after death, whereas the psychologist will "read" them as hallucinations. And, whereas the traditional Chinese "read" certain fossil teeth as dragons' teeth, the palaeoanthropologist, armed with the theory of evolution, sees them as remains of ancient apes or hominids. In short, the raw datum is no evidence: it becomes evidence when suitably interpreted in line with some of our background knowledge. (cf. Bunge, 1967b.)

We summarize the preceding observations into the following definition. An empirical datum *e* constitutes *empirical evidence* for or against a proposition or a proposal *p* (another datum, a hypothesis, a plan, a value judgment, etc.) if, and only if, (*a*) *e* has been acquired with the help of empirical operations accessible to public scrutiny (rather than made up, conjectured, taken from authority, or obtained by allegedly paranormal means): (*b*) *e* and *p* share referents (or predicates); (*c*) *e* has been interpreted in the light of some body of knowledge, and (*d*) some regular association (law or rule) between the properties represented by predicates in *e* and in *p* is (rightly or wrongly) assumed to exist.

The empirical operations referred to in clause (*a*) above are seldom purely empirical, particularly in modern science and technology. Thus the land surveyor employs scientific instruments, such as theodolites, together with geometry. Physicists, chemists and biologists use far more sophisticated instruments in conjunction with even more refined hypotheses. And, increasingly, they also use computers to drive microscopes, time the taking of pictures, control micromanipulators or servomechanisms, order the taking of measurements, and plot and even process the results of the latter. In all these cases a number of complex theories are involved in the design, performance, and utilization of empirical operations. In short, refined and exact empirical data are anything but theory-free perceptual reports. More in Section 3.

Data are seldom error-free. In particular, quantitative experimental data are likely to be subject to errors of two kinds: systematic (deriving from bias or defective design) and random (deriving, e.g. from random thermal motion and random external perturbations). We shall return to this point in Section 3. Let us now note only that, because data may not be error-free, they must be checked instead of being taken at face value. The new (checking) run of empirical operations may be done with the same technique or, preferably, with a rival (equivalent or better) technique. (Thus the ages of terrestrial rocks are estimated with a variety of methods, such as radioactive decay, accumulation of helium produced by cosmic ray impact, and even models of the evolution of the solar system.) Furthermore, ideally the checking is done by independent workers in order to minimize personal bias. Calculations are parallel.

In sum, the results of observations, measurements or experiments are not to be accepted at their face value but must be interpreted and screened. In particular, numerical data must be corrected in a number of ways, e.g. for parallax, pressure dependence, and sampling—not to speak of bias or systematic errors. Once corrected, the data are subjected to statistical processing, which yields aggregate data such as averages together with random errors (or scatters). In the process some data get eliminated, either because they are outlying (hence likely to be effects of artifacts or bias), or because they are in flagrant contradiction with well-confirmed theories. (Some outstanding scientists, such as Ptolemy, Newton, Mendel, and Millikan, have been accused of fudging or doctoring data in order to save their pet theories. This accusation is somewhat unfair: every good scientist knows that no data are to be taken at their face value.) The net result of a run of empirical observations yielding numerical data is a table or schedule from which a graph can be constructed, which in turn suggests a function. In short, the entire process from raw data to final evidence is the following chain:

$$\textit{RAW DATA} \xrightarrow{\textit{Interpretation}} \textit{EVIDENCE} \xrightarrow{\textit{Correction}} \textit{CORRECTED EVIDENCE} \longrightarrow$$

$$\xrightarrow{\textit{Statstical processing}} \textit{AGGREGATED DATA} \longrightarrow \textit{PRESENTATION.}$$

Administrators are often reluctant to fund the checking of data and calculations: they tend to see it as wasteful duplication of research. Yet rechecking is of the essence of scientific research. Besides, strictly speaking there is never exact replication, for there are never two identical research teams working in exactly the same circumstances. If smart enough, one of the teams is bound to find something—a new fact, a new hypothesis, a new method, or a new problem—that the other missed. And the team engaged in checking the work of others is bound to find some errors in the assumptions, procedures, or results of the first team. The outcome may be a more thorough checking, perhaps to the point of demolishing the earlier work or even showing that it had been triggered by an ill conceived problem.

As a matter of fact checking and rechecking are not the prerogative of scientists and technologists. Every rational man checks before, while, and after he acts or thinks. The horseman (or motorist) checks his mount (or car) before mounting (or driving); the craftsman checks his tools and raw materials before working with them; the biologist checks his preparations and instruments before and after conducting his experiments; the theoretical scientist checks his assumptions and the results of his calculations. Checking and rechecking is of the essence of good craftsmanship and of the practice of science and technology, just as it is alien to pseudoscience and prescientific ideology.

Practical men must have appreciated the value of checking procedures and things for thousands of years, or else they would not have left descendants. But the realization of the value of checking ideas seems to have dawned only recently. The first proof of a mathematical statement seems to be only 2,500 years old, and the first scientific experiments were not performed until the 17th century. For thousands of years physicians have prescribed cures, judges passed sentences, and religionists pronounced dogmas, without sufficient evidence and sometimes with no evidence at all. Most of mankind has lived and continues to live affirming or denying, at best debating, ideas supposed to be so important that they were deemed to be above checking. Only the humble hunters or farmers, stonemasons or scribes, took it upon themselves to check some ideas about their own work while allowing their economic, political and cultural leaders to mislead, oppress and exploit them in the name of unchecked or false principles.

This situation has changed, at least in the sciences, technologies and some branches of the humanities. In these fields it is now recognized that all truth claims—such as "*p* is true" and "*p* is truer than *q*"—and all efficiency claims—such as "*p* is effective" and "*p* is more effective than *q*"—are to be justified or validated by some objective means or other. However, philosophers are still divided on the acceptable ways of justifying truth claims, and they have not reflected much on the ways of validating efficiency claims. Leaving aside intuitionists—for they care only for self-evidence—and conventionalists—for not being interested in truth—we recognize the following philosophical camps with regard to the problem of the justification or validation of truth claims: see Table 11.1.

Unanimism (e.g. Ziman, 1979) holds that intersubjective agreement is necessary and sufficient for validation. Counterexamples: (*a*) the agreement of a thousand theologians concerning the existence of a deity does not prove it; (*b*) radically new theories are likely to be initially rejected or ignored by the great majority. *Pragmatism* (e.g. James, 1907) equates truth with success and therefore accounts for neither. We all know that some successful doctrines are false, whereas some true theories have found no practical application. *Rationalism* (e.g. Leibniz, 1703) holds that ideas are tested by checking their coherence with a body of basic (and possibly innate) beliefs. But coherence is insufficient: think of any consistent ideology and of that of some madmen. Besides, there is no reason to exempt

TABLE 11.1
How different philosophies of knowledge view the validation of truth claims

Philosophy	*Necessary and sufficient condition for validation*
Unanimism	1 Consensus of experts
Pragmatism	2 Practice (individual or social)
Rationalism	3 Coherence with background knowledge
Empiricism	4 Positive evidence
Critical rationalism	5 Lack of negative evidence
Critical realism	6 Numbers 3 through to 5 above

the principles themselves from rigorous checking. Nevertheless rationalism has an important grain of truth, namely that coherence is necessary: we dismiss hypotheses that are blatantly inconsistent with data, as well as data that fly in the face of well-confirmed theories.

Empiricism (e.g. Reichenbach, 1938) too contains an important grain of truth: experience is indeed a (though not the) test of truth and efficiency. In particular, positive evidence for the predictions calculated with the help of a theory confirm the latter. *Critical rationalism* (e.g. Popper, 1959) agrees that experience is a test of theories (its only concern) but claims that only negative evidence counts (against), for positive evidence is too easy to come by. True, unsuccessful attempts to refute a theory (or discredit a proposal or an artifact) are more valuable than mere empirical confirmation. However, (*a*) the most general theories are not refutable, although they are indirectly confirmable by turning them into specific theories upon adjoining them specific hypotheses (Bunge, 1973b); (*b*) true (or approximately true) predictions are not that cheap, as shown by the predictive barrenness of pseudoscience; (*c*) positive evidence for the truth of an idea or the efficiency of a proposal, procedure, or artifact, does count: thus the US Food and Drug Administration will rightly demand positive evidence for the efficiency of a drug before permitting its marketing.

Critical realism is a sort of synthesis of rationalism (the coherence requirement), empiricism (positive evidence), and critical rationalism (negative evidence), plus the realist thesis that the theories in science and technology represent (poorly or accurately) parts or aspects of the real world. I submit that critical realism is the tacit epistemology and methodology of science and technology. True, there is never overall coherence because new ideas are bound to be inconsistent with some bits of background knowledge; but this only shows that the latter is changeable and that justification or validation is never final. True, all experience is partial and inconclusive; but it can be enriched and checked by further experience as well as by theory. True, lack of negative evidence is valuable; but it is not enough, particularly since it is not more certain than positive evidence. In sum, critical realism demands at the same time coherence with the (changing) background knowledge, substantial positive evidence, and lack of significant negative evidence. It demands it not only from science and technology but also from the nonformal branches of philosophy, namely ontology, epistemology, and ethics. This empirical constraint on philosophy allows one to write off, as mere phantasies, such doctrines as that the mind is immaterial, that all knowledge is a matter of convention, and that moral behavior is unaffected by society. We need not waste much time in examining the ingenious arguments offered to buttress such phantasies: what matters is that they do not agree with the facts—as shown by their incoherence with our background knowledge and the absence of any positive evidence for them. (More on critical realism in Ch. 15, Sections 2 and 3.)

Note that we have been concerned with truth and efficiency claims rather than with beliefs. (Recall Ch. 2, Section 3.2 on the difference between knowledge and belief.) On the other hand the currently fashionable epistemologies concern belief. In particular the so-called coherence theories (which are really views rather than theories) hold that a belief is justified only if it coheres with all the other beliefs in a given belief system; and the "foundation" theories add that those beliefs that are most certain are to be taken as the foundation of our knowledge. Such epistemologies, which constitute a version of traditional rationalism, are ideally suited to religious and political ideologies, for coherence is the most that such bodies of belief can claim. By the same token those epistemologies are unfit for science and technology: here we are supposed to know (however provisionally) that a hypothesis has a high degree of truth, a procedure a high degree of efficiency, or a machine a high degree of reliability, before we believe in their adequacy. And such knowledge must be an outcome of research, both empirical and theoretical, not just a matter of checking coherence with a body of beliefs.

We hold that the study of belief, though a legitimate concern of epistemology, must be conducted like the study of any other real process, namely empirically as well as theoretically. Belief is mainly a concern of individual and social psychology. An armchair study of belief, yielding an a priori theory, is necessarily poor and dogmatic: poor because it makes no use of experiment, and dogmatic because it does not care for empirical validation. Take for instance the traditional beliefs on the correlation between ideology and social class. No a priori speculation is an adequate substitute for an empirical investigation into the actual correlation between, say, belonging to the working class and sympathizing with socialism, or belonging to the petty bourgeoisie and voting liberal. (See, e.g. Boudon, 1967.) Another example: only empirical investigations have established that (*a*) many popular superstitions (e.g. belief in telepathy) are formed by the natural tendency to conjecture causal relations, even about conjunctions of events that are nothing but coincidences or statistical flukes (i.e. chance accumulation or thinning of events in random sequences), and (*b*) people who are properly trained in probability theory and statistics are less prone to forming such beliefs. (See, e.g. Tverksy and Kahneman, 1977; Falk, 1982.) In sum, only scientific research into belief can yield genuine knowledge of belief: the nonscientific study of belief yields only further belief. And only scientific or technological research can tell us under what conditions it is reasonable to hold, withhold, or reject specific beliefs. In short, first knowledge through research—in particular knowledge about truth and efficiency—then credence.

In conclusion, claims of truth or efficiency must be validated by some evidence. Evidence can be conceptual or empirical. (However, the support a factual theory lends a proposition or a proposal may be regarded as indirect empirical evidence. And an empirical datum is evidence for or against a proposition or a proposal just because some theory suggests so.) Evidence can be positive, negative, or inconclusive. And in principle neither positive nor negative evidence is definitive, if only because further research may show that it is inadequate.

2. TESTABILITY AND INDICATORS

2.1. *Testability*

A proposition will be said to be *empirically confirmable* if there is direct or indirect, actual or potential empirical evidence for it; and *empirically refutable* if there is direct or indirect, actual or potential empirical evidence against it. A proposition that is only confirmable, or only refutable by empirical data, will be said to be *testable*. Finally, a proposition will be said to be *strongly testable* if it is both confirmable and refutable, and *untestable* if it is neither. (Concepts are testable for relevance and power but not for truth: only propositions are testable for truth.)

Because empirical data are obtainable by certain means but not others, and only provided the state of the art has attained a certain level, testability is not an inherent property of propositions but is *relative* to the available or conceivable empirical means. It may happen that a proposition is testable by data of a certain kind but untestable by data of another; or that it is better testable by data of one kind rather than another; or that it is more testable than another proposition relative to a given body of data. In sum, testability comes in degrees and is relative to the (empirical and conceptual) test means. So, any theory of degrees of testability would have to elucidate expressions of the forms "The testability of p relative to means m equals t", "p is better testable by m than by m'", and "p is more testable than q with the help of m".

Note that we have made room for potential data or, what amounts to the same, for testability *in principle* alongside actual testability. For example, a historical hypothesis conceived to explain certain data (or their absence) is likely to suggest the search for new evidence of a certain kind, which search may stimulate the invention of new techniques or the application of techniques evolved in other research fields. Another example: it is not always possible to determine, with today's means, whether a certain enzyme is present in a given chemical system or organism, because the substrate-enzyme complexes are unstable and therefore short lived. So, many conjectures in biochemistry, though potentially testable, are not yet actually testable. (According to the well-confirmed Michaelis–Menten hypothesis, a reaction of the form $A \rightleftharpoons B$ catalyzed by C actually summarizes two reactions involving the substrate-catalyzer complex AC. They are: $A + C \rightleftharpoons AC$, which is reversible, and $AC \rightarrow B + C$, irreversible. If the corresponding rate equations fail, we hypothesize that a different or a further catalyzer is at work.)

We have also included *indirect* empirical evidence, i.e. evidence through some intermediary body of knowledge. For example, "There have been dinosaurs" is not directly testable, for there are no living dinosaurs nowadays but only certain fossil bones, eggs, and footprints. The hypothesis itself allows one to interpret such data as evidence for it. (Other historical hypotheses are parallel.) However, far from being a stray conjecture, the dinosaur hypothesis is part of the vast body of evolutionary biology, which in turn is consistent with the rest of biology as well as with geology. Or take the hypothesis of interactionist mind-body dualism, namely "Mind and body are distinct though mutually interacting substances" (Cf. Popper and Eccles, 1977.) This hypothesis is confirmable because it accommodates any conceivable mental event; by the same token it is not directly refutable. However, the hypothesis is indirectly refutable, namely by showing that it is incompatible with physiological psychology and even with physics. Indeed any action of an immaterial mind on matter (e.g. a brain) would violate the principle of conservation of energy. (Cf. Bunge, 1980a.)

Other hypotheses are confirmable but irrefutable in principle, hence only weakly testable. For example, the hypothesis of hypnotic trance is immune to refutation because, if the subject obeys instructions, he is declared to be in such a state, whereas if he does not, he is said not to have been properly hypnotized (Barber, 1970). Another hypothesis of the same methodological type is "All persons seek to maximize their utilities". This axiom of utility theory (and of much of neoclassical economics) is confirmed, never refuted, by whatever any person does: even altruism and suicide can be interpreted as maximizing the person's moral if not economic utilities. Therefore it is weakly testable.

Finally let us exemplify the notion of an untestable proposition. Utter untestability can be due to either imprecision or the positing of inscrutables. Gestalt psychology is an example of a system of propositions that, because of their vagueness, are hardly testable (Claparède, 1934, p. 145). In such cases one does not know exactly what is to be tested. However, some imprecise propositions are worth being exactified and rendered testable. (*Example*: "Curiosity can be smothered or trained".) Note that exactness is necessary but not sufficient for testability. Indeed any proposition positing the existence of inscrutable entities is untestable even if precise. Here is a random sample of untestable propositions of this kind. (*a*) "We are surrounded by things that are unknowable in principle". (Kant's thing in itself was of this kind for him.) (*b*) "Physical space is embedded in a higher dimensional space, but we happen not to have access to the extra dimensions". (*c*) "There are things deprived of energy". (Such things could not possibly exchange energy with ordinary things, such as particles or fields, so they would go undetected.) (*d*) "Good people go to heaven, bad ones to hell".

There can be no empirical evidence for or against vague propositions or for propositions positing inscrutables. The same holds for some counterfactual conjectures, such as "If Einstein had not invented general relativity then someone else would have done it". All such propositions are empirically untestable. However, they may be discarded by the simple philosophical manoeuvre of asking their propounders "How do you know?" or "What evidence have you got?" (Parenthetically this mode of refutation is not available to Popper (1963), who regards such questions as inappropriate and, in general, matters concerning our information sources as unimportant.)

Let us now examine certain kinds of hypotheses whose methodological status seems uncertain: partial differential equations, ad hoc, existence, continuity, possibility and probability hypotheses, and estimates of nuclear weaponry capability. *Partial differential equations*, a standard tool of physicists, astronomers, engineers and many others, have infinitely many solutions. This richness is theoretically valuable but methodologically embarrassing, for it renders such equations testable in too many ways. (*Example*: any differentiable function of the argument $x - vt$, where x and t are independent variables and v a constant, solves the equation $(\partial u/\partial t) + v(\partial u/\partial x) = 0$. The latter may be partially interpreted as "For every entity k of species K, the u-ness that k gains or loses in the course of time is compensated for by a loss or gain in the u-ness of k effected by a change in place". Among others, field-like and particle-like solutions of the equation exist. For a detailed analysis of a theory generated by that hypothesis see Bunge (1967d).)

In other words, a partial differential equation offers a large target to empirical tests, but the results of these are inconclusive for bearing on the solutions not on the equation itself. (The situation is even worse with regard to the Lagrangian functions that, via extremum principles, generate those equations. Indeed every equation of motion or field equation can be generated by any of an infinity of such functions.) In other words, not the equations themselves together with their infinitely many consequences, but only some of the latter are confirmable by empirical data: see Figure 11.1. If data of one kind fail to confirm a given solution, then data of another may confirm it. Likewise if data of a given kind refute one of the solutions, they may confirm another. So, the original equation itself can hardly be said to be refutable—at least not until all its solutions have been tested. However, in practice the decision is considerably eased by three considerations. One is that a partial differential equation is usually one component of a whole problem system that contains also a number of restrictions such as initial or boundary values, which restrictions narrow down considerably the set of possible solutions. Another is that not every solution is interpretable in suitable factual terms; those which are not so interpretable are just

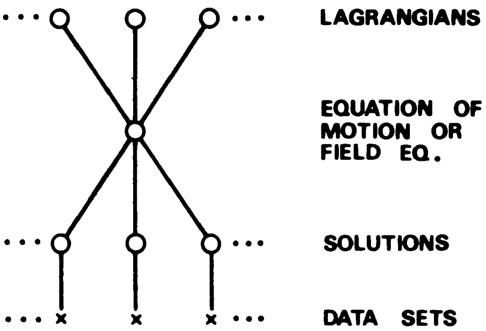

Fig. 11.1. One and the same equation of motion (or field equation) is derivable from alternative Lagrangians, and has different solutions. Data of a certain kind may favor one such solution.

dropped. A third is that the equation entails not only its own solutions but also a number of additional theorems—perhaps conservation laws—some of which are empirically testable. Nevertheless the evaluation of such high level hypotheses is anything but straightforward.

Next in our list of hypotheses that arouse some methodological unease are *ad hoc* hypotheses. An *ad hoc* hypothesis is a particular assumption, i.e. one covering a rather narrow range of facts. We distinguished two kinds of *ad hoc* hypotheses: *bona fide* and *mala fide*. (Ch. 8, Section 4.2.) A *bona fide ad hoc* hypothesis is normally offered to represent facts of a certain kind and it is independently testable. For example, to complete his theory of the circulation of the blood Harvey had to conjecture the existence of tiny vessels, that remained invisible during his lifetime, connecting arteries and veins; this hypothesis was confirmed later on with the help of the newly invented microscope. On the other hand a *mala fide ad hoc* hypothesis is designed exclusively to protect another hypothesis, or a theory, from refutation: it is a cyst. A classical example is Freud's repression hypothesis, which saves the Oedipus complex fantasy in case the individual fails to exhibit such "complex". Another is the parapsychologist's claim that the presence of skeptics inhibits the mind reader and the clairvoyant. *Mala fide ad hoc* hypotheses are to be avoided because they block the test process. On the other hand there is nothing wrong with *bona fide ad hoc* hypotheses. The earth sciences teem with testable hypotheses that, presumably, hold only for our planet, and are therefore both *ad hoc* and *bona fide*.

The *existential hypotheses*, i.e. conjectures of the form "There are *F*'s", are logically modest but ontologically ambitious and therefore methodologically tricky. Indeed they can be confirmed by exhibiting instances but they are hard to refute for, if an effort to find *F*'s fails, one may still hope that more strenuous efforts will meet with success. But of course no such efforts will be made unless there is some evidence, empirical or theoretical, for the existence of *F*'s. Columbus had both when he undertook his first voyage; so had Le Verrier and Adams when they predicted the existence of Neptune, and Hertz when he predicted the existence of electromagnetic waves.

Mere argument neither proves nor disproves existence—except of course in theology. In formal science existence is either postulated or proved from postulates with the help of logic. In factual science and technology existence conjectures are supported or undermined by both theory and empirical evidence. The former suggests, the latter establishes more or less conclusively. And in a science-oriented philosophy existence claims should be treated in like manner: they should be postulated or proved rigorously in the case of constructs, and supported by empirical evidence in case they concern concrete things. No matter how seductive an argument for the existence of deities, disembodied minds, propositions in themselves, and the like, it will cut no ice in scientific philosophy unless it can be supported by empirical evidence.

To be sure, theoretical considerations in science or technology, though powerless to prove or disprove the existence of any concrete thing, can render an existence hypothesis likely or unlikely, hence worthy or unworthy of being investigated. This they can do by showing that the given existence hypothesis is necessary for consistency or, on the contrary, leads to contradiction—as was the case with the aether hypothesis. Or such theoretical considerations may show that, if the entity in question were to exist (or not to exist), certain well-confirmed theories would fail. Thus no physicist can admit the existence of an entity that fails to conserve energy, or the nonexistence of a massive body, even if invisible, at a focus of the elliptical orbit of a celestial body. Still, the most conclusive proof of existence, whether in mathematics, science, or technology, is to exhibit a specimen of the object whose existence has been postulated.

Being empirically irrefutable, existence hypotheses have been declared untestable and therefore unscientific or metaphysical (Popper, 1959; Lakatos, 1978). However, this only goes to prove that testability is not to be equated with refutability. First, if we do find an *F* we have proved (until new notice) that there are *F*'s. (To be sure such evidence is not final—but then no empirical evidence is.) Second, the refusal to admit existential hypotheses entails giving up some of the most powerful and best confirmed scientific theories. Take for instance the core of classical mechanics (or of its relativistic generalization): "For all bodies and all forces and stresses, at all places and all times, *there exist* reference frames relative to which the rate of change of the linear momentum (or the momentum density) equals the body force plus the divergence of the stress tensor". Finding one reference frame relative to which this equation of motion holds, confirms the hypothesis; such a frame is called *inertial*. And finding any number of frames relative to which the hypothesis fails (e.g. our own planet) serves only to indict the frames as being non-inertial, not the hypothesis as false. Third and most important, the refusal to countenance existence hypotheses just because they are irrefutable, though consistent with conventionalism and pragmatism, is inconsistent with any realistic epistemology, for which the aim of science is to understand existents (and real possibles). This epistemology is inherent in the careful formulation of any scientific theory, where one begins by assuming that the reference class of the theory is nonempty—i.e. that the entities described by the theory *exist* on their own.

Still, could it not be that a theory passes some empirical tests and yet some or even all of its referents do not actually exist? After all there are plenty of historical examples of theories postulating nonexisting objects, such as caloric, aether, and magnetic monopoles. A first answer is that no final certainty is attainable in this case or in any other: the most one can obtain is solid though corrigible evidence. Second, a realist epistemology, one regarding the postulated entities as possibly existing rather than being fictions, will be more helpful than either an idealist or a conventionalist one. For, even if the objects postulated by the theory prove to be ghostly, the search for them is likely to yield some knowledge. (For example, the failure to find magnetic monopoles confirms once again standard electrodynamics.) Thirdly, there are no separate and fool-proof existence tests. In short, existential hypotheses are at the very core of science although, being only confirmable but irrefutable, they are not strongly testable.

Continuity hypotheses are of the form "The function F, which represents the property P of things of kind K, is continuous (or piece-wise continuous) over the domain D". Obviously, no measurement could possibly provide a direct test of such a hypothesis, for only a finite number of values of a function can be measured. So, we must resort to indirect empirical tests, such as those bearing on some consequence of the hypothesis. An example will elucidate this point. Suppose the available data are consistent with the following alternative hypotheses concerning a certain force: (*a*) the force varies continuously with the inverse of the distance, and (*b*) the force varies with the inverse of the distance when the latter is a rational number but is zero otherwise. To decide between the two hypotheses we may measure the work done by the force along a certain stretch. The result will be a nonzero quantity in the first case and zero in the second. (The work equals the definite integral of the force over the given distance. The integral is null in the case of the second function because it is defined on a set of zero measure.) In sum, continuity hypotheses are empirically testable though in an indirect manner. Moreover they are not only confirmable but also refutable: indeed any significant discontinuity in the corresponding property of their referents will refute them.

A *possibility hypothesis* is, of course, one stating that facts of a certain kind are possible. (In turn, real possibility equals compatibility with law: see Vol. 3, Ch. 4.) In science and technology possibility hypotheses are stated on theoretical considerations. For example, a spectral line or band is declared possible if the corresponding atomic or molecular transition is compatible with the atomic or molecular laws, and "forbidden" otherwise. And a technological project is declared to be in principle feasible if it involves no violation of any known laws—otherwise in principle unfeasible. Clearly, possibility hypotheses are confirmable but irrefutable on purely empirical grounds. The only possible empirical evidence relevant to a possibility hypothesis is of the positive kind: we prove that X is possible the moment we see X happen either naturally or through human intervention. (If X fails to happen we can still argue that it is too soon to write it off—or that, given the changed circumstances, it is no longer possible.) Actuality is then the only empirical evidence for possibility. (But this does not mean that actuality is the meaning of possibility, e.g. that probabilities mean frequencies.)

As for *probabilistic hypotheses*, they all pose the following problem. If the set of events under observation (i.e. the sample space) is smallish, whatever happens may be regarded as confirming the hypothesis; and if nothing happens the hypothesis cannot be said to have been refuted, for accidental crowdings and thinnings are of the essence of chance. For this reason a number of authors, among them Popper (1959), have regarded probability hypotheses as untestable or nearly so. However, this difficulty disappears as soon as huge masses of events become available: in such cases the probability of any deviation between probability and observed relative frequency approaches zero. This is actually the case with the various probabilistic hypotheses involved in particle and field physics, statistical mechanics, quantum chemistry, genetics, and to some extent social science as well. Thus even if the probability of an individual atomic collision (or genic mutation, or conversion of proletarian into tycoon) is extremely small, collisions (or mutations or dramatic changes in economic power) will happen in large aggregates of individuals or in the very long run.

Randomness is characterized not only by stable (or regularly varying) long run frequencies, but also by short term fluctuations, i.e. occasional high or low scores—e.g. streaks of good or bad luck. Only if the scores are consistently higher or lower than the calculated probability can we infer that the latter has been refuted. Typically parapsychologists ignore this peculiarity of random events when claiming that the psychic powers of their sensitives is "above chance" during certain periods and then—particularly when watched by skeptics—decline. In short, probabilistic (or stochastic) hypotheses are empirically testable by huge masses of like events: a single unfavorable case will not refute them. However, this only shows that we must make a philosophical decision: either we give up some of the deepest and best confirmed scientific theories—such as the quantum theories and genetics—or we reject any methodology that regards probabilistic hypotheses as untestable, and therefore unscientific, just because they are not tested the same way as nonprobabilistic hypotheses.

Let us now discuss the testability of hypotheses concerning the efficiency of weapons or strategies of certain kinds. As is well known, the Nazis subjected Britain to an intense bombing—only to unite and strengthen the Britons as well as to elicit universal sympathy and solidarity with them. Ignoring this teaching, subsequently the U.S. and British air force subjected Germany to an intense bombing in order to destroy the German economy and, in particular, its arms industry. This operation went on for nearly three years without the slightest indication of its effectiveness. Shortly after the war the U.S. Strategic Bombing Survey found that the bombing had been a dismal failure or worse, namely counterproductive. In fact the German arms production increased under the bombing: the production of tanks tripled, and that of planes doubled between 1942 and 1945. (Apparently the military did not relish this finding that refuted one of its most cherished dogmas: see Galbraith, 1981, Ch. 13.) Nowadays we face an even tougher problem. For the first time in history man has produced engines, namely intercontinental missiles with nuclear warheads, that are untestable. Indeed, if any of them were put to the test World War III could start, and presumably there would be nobody left to evaluate the damages. So, nobody can know exactly what those engines are worth—except of course in terms of the impoverishment of our lives. In this case speculating over the effectiveness of such artifacts is preferable to testing them. And in any event it is ironic that technology, with the help of testable and moreover well-confirmed theories, should have produced untestable artifacts.

Let us now compare constructs of different types as to testability. Obviously, such comparison is greatly facilitated if the constructs represent the same aspect of things of the same class, such as radiating antennas. Consider on the other hand the equivalence "For every x, if x is an organism, then: x has genotypic trait G iff x has phenotypic trait P". Since phenotypes are more easily recognizable than genotypes, the LHS of this equivalence is harder to test than its RHS. Equivalents are not necessarily equitestable. (*Methodological moral*: Logic is a poor guide to investigate testability.)

Assuming unlimited empirical means, singular propositions are better testable than universal ones, which in turn are more fully testable than hypothetico-deductive systems (theories). Thus "That antenna is radiating electromagnetic waves of such and such wavelengths in such and such direction" can be checked more fully than any particular formula of the theory of antennas, which theory is in turn even harder to test. Not that testing a singular proposition, i.e. one concerning an individual, is always plain sailing. Think of the extraordinary difficulties met in testing singular propositions of the form "That astronomical object is a black hole", and "This organism has just undergone a mutation". In neither case do observations suffice: in both cases the tests are extremely indirect and their results rather inconclusive.

General propositions are even harder to test than the corresponding singular propositions if the former concern a large or variable collection of individuals, as is the case with any basic law statement. True, in principle a single unfavorable case refutes the claim to universality—provided the evidence is reliable. But such result does not dispose of the generalization. In fact, though false in a given range, the generalization may hold in another, and this can be established only by continuing the tests after the first disconfirmations are in. Never mind the real motives of the scientist or technologist performing such tests: he may wish to confirm or to disconfirm. What matters is that the generalization can be pronounced false if nearly all the tests, over the whole range, are negative, and true (to some extent) in a given range if nearly all the tests in that range turn out to be positive. However, it may also happen that the tests are inconclusive, in which case a new, more precise testing technique may have to be tried.

Paradoxical as it may sound, single generalizations are in general harder to test than generalizations included in theories. The reason is that, whereas an isolated generalization can count only on the evidence bearing directly on it, a hypothesis belonging to a hypothetico-deductive system can also count on whatever evidence favors other components of the system. In other words, a systemic hypothesis can enjoy both direct and indirect empirical support. See Figure 11.2. Such indirect support is multiplied if the theory in question agrees with other theories in the same or different fields. For example, whereas a biological (neurophysiological) theory of mental functions can be supported by neuroscience and, indeed, by the whole of biology, a dualistic theory of mind cannot enjoy such support.

A theory is composed of infinitely many propositions (Ch. 9, Section 1.2). Therefore it can never be exhaustively tested: one must always confine oneself to testing a finite subset of the infinite set of propositions. Now, scientists do not test arbitrarily selected theoretical propositions but only those that interest them most—e.g. because they are the most novel—or that lend themselves more easily to tests. This tends to produce clusters of frequently tested propositions, alongside with pockets of propositions that are seldom if ever checked. There would be nothing wrong with this procedure if all the propositions of a theory had the same truth value, but this is not the case. Even highly successful theories, such as quantum electrodynamics, contain false propositions alongside others which are true or nearly so.

A solution to this problem would be to treat theories the way concrete populations are handled, namely to draw random samples. We might collect all the known and testable propositions of a theory, assign them random numbers, and draw lots. In this way the theory could be likened to

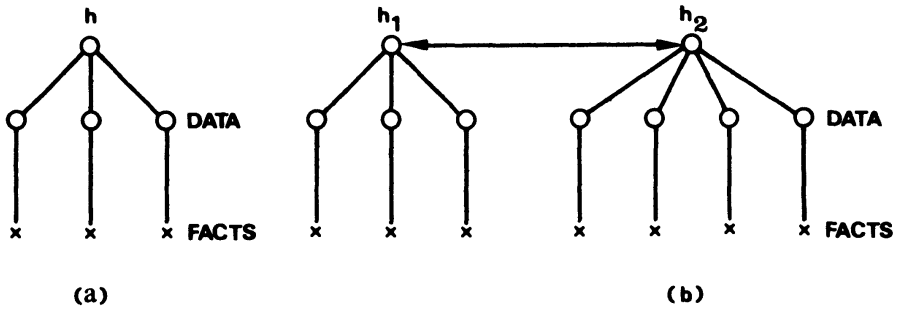

Fig. 11.2. The empirical support of hypotheses. (*a*) A single hypothesis is supported or undermined only by the facts it refers to. (*b*) A hypothesis belonging to a hypothetico-deductive system (theory) is controlled not only by direct evidence but also by whatever data are relevant to the hypotheses to which it is logically related.

a bag containing infinitely many marbles of unknown colors in unknown proportions. In the simplest case there would be only two colors, say white (T) and black (F), in unknown proportions. A test of the theory could thus be likened to the extraction and examination of marbles, one at a time and without replacements—except of course when one has reason to suspect some data and thus repeats the test. What are we to conclude if 100, 10,000 or even 1,000,000 balls turn out to be all white (T) or all black (F)? Strictly speaking *nothing*, for (a) there are still infinitely many unchecked marbles in the bag, all of which could prove to be black (F) in the first case and white (T) in the second; and (b) although the tested sample is a random one, the original population—in turn a finite subset of the set of all the propositions in the theory—was not, for we can know only those propositions in the theory that, for some reason or other, happen to have attracted the attention of theorists. And if the outcome of our test is that w marbles out of a total of n turned out to be white (T) and b black (F), all we can say is that the degree of confirmation of the theory (up to the nth test and with the given means) is $w/(w+b)$. But, for the above reasons, this datum is not very helpful except when the total number of tests is very large and the degree of confirmation is either nearly 1 or nearly 0. In the first case we may conjecture that the theory is true, in the second that it is false. But of course we must keep an open mind, as a further run of tests may force us to change our evaluation. Truth values, like the value of money, tend to depreciate in time.

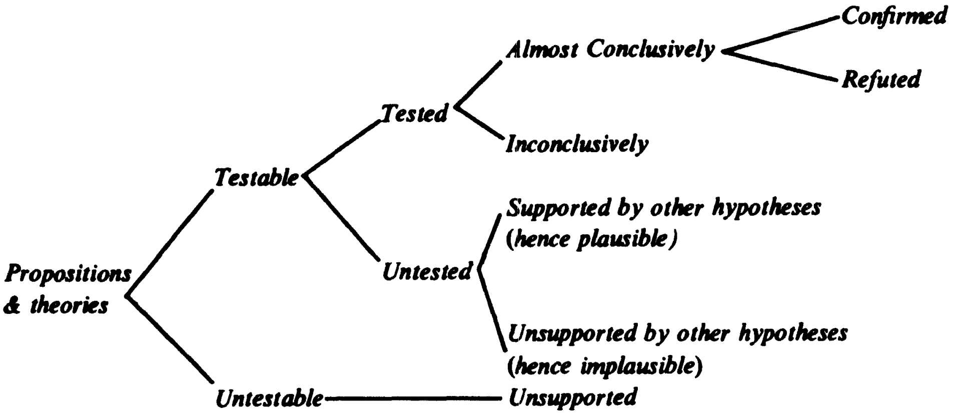
If theories in general are hard to test, the most general among them are the hardest. To be sure, if testable at all they are confirmable, but not necessarily refutable as well. Take for instance the most basic formulas of classical (or relativistic or quantum) mechanics. Undoubtedly they do have some general testable consequences such as the conservation theorems. However, in order to test any basic hypotheses we must adjoin them specific assumptions concerning the precise composition, environment, and structure of the system in question, be it atom, binary star, or machine, for we will contrast the theory with data concerning objects of certain kinds, such as atoms, binary stars, or machines. That is, we must conceive of a model object couched in the language of the theory: one specifying, say, what the components of the system are and how they interact with one another and with the environment. (Shorter: we must specify the Hamiltonian or the forces and stresses, the constraints and the initial and boundary conditions, and the constitutive relations characterizing the type of matter in question.) The outcome of this theoretical activity is a model, or specific theory, representing the object in question. This, not the general theory to which it is bound, is put to the test (Bunge, 1973a).

Since models (or specific theories), not general theories, are the ones that are subjected to empirical tests, the outcome of the latter, if negative, does not tell us unambiguously what went wrong: whether the general theory or the special assumptions adjoined to it. To be sure, uncertainty shrinks if a variety of models using the same general theory either succeed or fail. But even so some uncertainty remains. The only clear cut cases are exceptions: when none of many models grafted on to a general theory is confirmed, we are justified in blaming the latter; whereas if only a few fail, we blame the special assumptions. This methodological predicament is common to all extremely general theories. Thus the theory of evolution is so general as to be confirmable but not refutable. It becomes also refutable, and thus strongly testable, only when the genetic composition and the environment are specified, i.e. when applied to a particular lineage, over a long period of time. (See Bunge, 1978b.) What holds for the extremely general scientific theories holds, a fortiori, for the philosophical ones that concern the real world or our knowledge of it. Only the specific scientific theories based on those philosophical theories are strongly testable (Bunge, 1973b).

Let us remember that every factual theory, whether scientific, technological, or philosophical, has two ingredients, namely the formalism and the interpretation. So either or both can go wrong, and in some cases a correct interpretation can somehow compensate for a defective formula or conversely. Therefore if the theory is disconfirmed we may try altering portions of its formalism, its interpretation, or both. And although this is an eminently theoretical job, it cannot be conducted except in the light of the available empirical evidence. For example, there is consensus that the mathematical formalism of quantum mechanics is essentially correct, but there is disagreement about the correct physical interpretation of the theory. Yet it is possible to choose among the existing rival interpretations on both theoretical and empirical grounds. In particular, we can refute the subjectivistic interpretation of quantum mechanics just by noting that, if it were correct, (*a*) the theory would include psychological concepts (such as those of the state of knowledge and the intentions of the experimenter)—which it does not; consequently (*b*) psychological data (about the observer) would be relevant to both calculations and measurements—which they are not; and (*c*) the outcome of the empirical tests would depend critically on who performs them—which it does not. (More in Bunge (1967c) and (1973a).)

Finally, what about metaphysics or ontology? If defined as an untestable attempt to account for the world, the problem of the testability of metaphysics does not even arise. In this case metaphysics may be granted some heuristic value but it must be denied any truth value. To be sure, most of traditional metaphysics is untestable when intelligible at all. However, metaphysics can be overhauled with the help of exact tools and in such a manner that it becomes continuous with science: see Volumes 3 and 4. For example, it is possible to build a general and exact theory of spacetime compatible with contemporary physics, and a general and exact theory of mind harmonizing with contemporary physiological psychology. Therefore the initial definition must be altered to read: Metaphysics (ontology) is a family of (indirectly) testable theories about the world.

We close this section with a classification of factual propositions and systems of such with regard to their testability.



Propositions & theories
Testable
Tested
Almost Conclusively
Confirmed
Refuted
Inconclusively
Untested
Supported by other hypotheses (hence plausible)
Unsupported by other hypotheses (hence implausible)
Untestable
Unsupported

2.2. *Indicators*

According to radical empiricism scientific theories are data summaries, i.e. they have an empirical (not just factual) content. If this were true, then the testing of any such theory would be a straightforward contrasting of propositions of the theory with the corresponding data. But that is not true: scientific theories have a *factual* reference but, unless they actually describe human experience, they have no *empirical* content.

That scientific theories are not just data summaries, or even mere devices for churning possible data (e.g. predictions), is shown by the fact that they do not refer to the observations, measurements, or experiments aiming at testing them. Thus theoretical mechanics does not describe dynamometers (although it helps design and explain them), and genetics does not describe electron microscopes, which are employed in imaging chromosomes. Instead, scientific theories contain theoretical concepts lacking a counterpart in sense experience, such as those of continuity, free motion, strain, electric field intensity, valence, DNA, neural connectivity, GNP, and theory. As a consequence scientific theories contain propositions without an empirical counterpart. A simple example is that of the "principle" of inertia, a cornerstone of physics and a theorem of classical and quantum mechanics. The "principle" has a factual content since it refers to bodies or particles. But it has no empirical content because it holds only in the absence of any action upon the body of interest, in particular if no empirical tests are performed on it: in short, it does not refer to any empirical situation.

Scientific theories are factual: they concern (authenticated or putatively) real things with properties that are mostly beyond the reach of perception though not of intellection. Therefore they rarely contain empirical concepts. Yet, if they are scientific, theories can be anchored to experience by adding to them links between some theoretical concepts and some concepts having an empirical counterpart. For example, electrodynamics does not deal with pointer readings but gets its support from such operations by virtue of certain formulas that link the field intensity to the torque in a meter. Likewise to test his theories the psychologist looks for behavioral and physiological manifestations of mental phenomena. The physician uses a whole battery of symptoms or diagnostic signs (among them the "vital signs") to evaluate the state of health of his patients. And the economist employs an array of economic and social indicators, such as the steel production and the rate of unemployment, to estimate the state of the economy. All such observables are conjectured, rightly or wrongly, to be lawfully linked to unobservables, so that a measurement of the former allows one to infer (sometimes calculate) the value of the latter. See Figure 11.3.

These observable-unobservable links used to be called *operational definitions* (Bridgman, 1927). But, since they are hypotheses to be tested, not conventions, they had better be called *indicator hypotheses*. An indicator hypothesis is a hypothesis relating an unobservable property of a thing to an observable property of the same thing or of a second thing lawfully linked to the first. The hypothesis may be precise or imprecise, according as it is formulated mathematically or not, but in any case it must

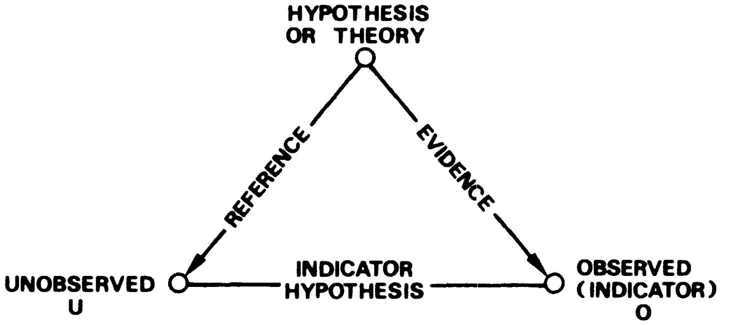


Fig. 11.3. The unobserved-observed (or indicator) relation is expressed by an indicator hypothesis allowing us to infer unobservable things, properties, or events from observation. (Adapted from Bunge (1967a).)

be fully testable and may therefore be improved or replaced with a better one. Far from replacing theoretical concepts, indicator hypotheses are added to factual theories in order to render them testable. Such enrichment of theories in preparation for their empirical tests is sometimes called *operationalization*. A hypothesis or theory that cannot be operationalized, or cannot be logically linked to any operationalizable constructs, is sheer speculation and therefore does not qualify as scientific or technological.

Many, perhaps most of the indicators used in ordinary life and in some professions are imprecise and empirical and therefore unreliable. The cook takes a potato at random from the pot and pricks it with a fork to find out whether it is boiled; but the potato could be rotten, or it could be the only one from the new crop. The naive person takes certain gestures of another as tokens of sincere friendship, while actually they may have been calculated to produce this impression. He is using incorrectly the true generalization "For every x and y, if x is friendly towards y, then x gives y tokens of friendship" to infer friendship from a smile, a kind sentence, or a gift. He is of course indulging in a logical fallacy. A more experienced person would wait for the outcome of further tests; and in future there may be precise philometers.

Typical forms of ambiguous indicator hypotheses are *If U then O*, and *If O then U_1 or U_2*, where O stands for an observable property and the U's for unobservables. In the first case the presence of an indicator (observable) is only a necessary but not a sufficient condition for the corresponding unobservable. In the second case the indicator points ambiguously to two (or more) unobservables. In both cases the indicator–unobservable relation is one–many rather than one–one, and therefore unreliable. Thus the long backlog of a scientific journal may indicate either its prestige, or the scarcity of outlets in its field, or a sudden swell of interest in it, or the poverty of the supporters of the journal, or a deficiency in its administration. Only an independent inquiry may discover the cause(s) of the backlog. Another example: if a political candidate is beaten at the polls, this may indicate that he was not well known or too well known ;that he spent too little money or too much; that he was regarded as too dumb or too smart; that he represented the interests of a minority or that most people failed to understand that he did represent them—and so on.

There are two ways of dealing with ambiguous indicators. One is to multiply them, i.e. to employ a whole battery of mutually consistent indicator hypotheses, hoping to reduce the uncertainty. For example, a physician observes symptom O_1, which may indicate causes U_1 or U_2. But he also observes O_2, which never accompanies U_2, so he infers that U_1 is the cause. Even so he may order a few laboratory tests, not only to make sure that U_1 is the cause but also to estimate its strength. Whereas some of these tests are direct, others are indirect, i.e. they yield further indicators. Thus an X-ray plate is direct because it images the suspect bone or organ. On the other hand most of the results of blood tests are indirect.

A second way of reducing uncertainty about unobservables is to conjecture and test one–one indicator hypotheses, i.e. to substitute 1:1 functions for relations. If we suspect or have established that the observable O is a certain 1:1 function f (e.g. a linear function) of the unobservable U, then by inverting f we may compute U from the measured O values, for $U = f^{-1}(O)$. In this case we say that *O measures U*. (Caution: indicators measure unobservables, but only an effective measurement operation can pin numbers on either.) Needless to say, it is desirable, though not always possible, to have different measures of every important unobservable, so that one may check the other.

Here are a few simple examples of functional hence unambiguous indicator hypotheses. (*a*) The angle of deviation of the pointer in an ammeter connected in series measures the intensity of the electric current in a circuit. (*b*) The intensity of radioactivity can be measured by the discharge of charged bodies, for this discharge is caused by the ionization of the gas surrounding the radioactive sample. (*c*) The quantity of ACTH (adrenocorticotropic hormone) released is an indicator of the activity of the adrenocorticotropic system, which in turn is a measure of stress. (*d*). The time at which two related species diverged is proportional to the fraction of number of kinds of protein that they fail to share: this hypothesis is the basis of the "molecular clock" method for measuring inter-species distances. (*e*) The average length of a bus queue is proportional to the time elapsed since the last bus stopped by.

Whereas some indicator hypotheses have sound theoretical bases and have been abundantly confirmed, others are tentative conjectures with insufficient empirical support. The hypothesis (*a*) underlying all ammeter readings is of the first kind, whereas the hypothesis (*b*), on which the "molecular clock" method is based, is of the second kind. Should rapid speciation events, taking between 5,000 and 50,000 years (like the one reported on by Williamson (1981)), prove frequent, then hypothesis (*b*) is likely to hold only, if at all, for very long periods, of the order of one million years. Another indicator hypothesis that has recently been challenged is the one according to which genotypes are mapped onto phenotypes in a one to one fashion, so that, given a genotype, the corresponding phenotype can be inferred, and conversely. This simple and widely accepted hypothesis is false. First, there are the cases of evolutionary convergence, showing remarkable morphological similarities (e.g. between cetaceans and fish) hiding profound organismic and therefore genetic differences. Second, there are species (or superspecies) within which an extensive karyotic diversity is found underneath little morphological differentiation. (A striking case is that of the spiny rats from Venezuela, the number of chromosomes of which varies between 24 and 62: Benado *et al.*, 1979.) In short, the genotype-phenotype relation is many to one, which renders phenotype a highly unreliable genotype indicator.

Reliable indicators help operationalize a theory, i.e. prepare it for empirical tests, in the following manner. Call $\mathcal{T}$ the general theory to be tested and S the set of subsidiary assumptions specifying particular features of the referent (e.g. the composition, environment, and structure of a system). From $\mathcal{T}$ and S we build the (bound) model $\mathcal{T}'$ of the referent, which is to be subjected to tests. Enter the set I of indicators built with the help of the antecedent knowledge and $\mathcal{T}$ itself. Enter also the set E of available empirical data concerning the referents of the theory and relevant to the latter. Such data are somewhat remote from the theory: for example they may consist of behavioral information, whereas the theory is about mental states. This theory-experience gap is bridged by the indicator hypotheses I: they allow us to "read" behavioral changes in terms of mental processes, benefits from costs and sale prices, or what have you. We may call this a *translation* of the available data into the language of the theory. These translated data E', that follow logically from E and I, are fed into the model $\mathcal{T}'$ to yield the translated model $\mathcal{T}''$. Finally, this result is

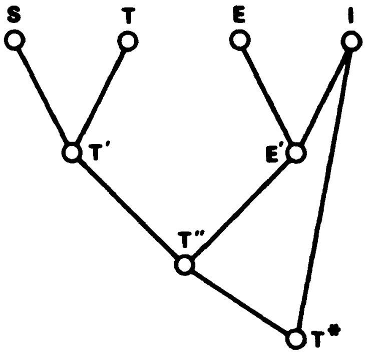

Fig. 11.4. The operationalization of a theory T. T and the specific assumptions S yield the model T' of the referent. The data E are translated into the language of the theory with the help of the indicator hypotheses I: the result is E' which, together with the model T', yield the testable consequences T''. Finally, these are translated back into the language of experimental science by means of the same indicator hypotheses I, to yield T^*, which is ready to be confronted to fresh data.

translated back into the language of experience by means of I. That is, $\mathcal{T}''$ is joined to I to entail $\mathcal{T}^*$, the operationalization of the theory, or rather of the (bound) model $\mathcal{T}'$. Hence not $\mathcal{T}$ itself but some consequences of $\mathcal{T}$ together with the subsidiary assumptions S, the data E, and the indicator hypotheses I, face whatever fresh experience may be relevant to $\mathcal{T}$. See Figure 11.4.

Our view of theory testing is at variance with the received view among philosophers of science. According to the latter a theory is a hierarchy of hypotheses, the highest placed of which would contain theoretical concepts without a directly observable counterpart. The lowest level hypotheses, instead, would be mere generalizations from observable facts and would therefore contain only observational concepts. And there would also be mid-level hypotheses containing concepts of both kinds. Moreover the relation between hypotheses of different levels would be strictly logical: the higher level hypotheses would imply the lower level ones. Therefore, theories would be tested by checking their lower level components, i.e. the logical consequences of their axioms. Such consequences would be in finite numbers because they are allegedly the inductive generalizations that prompted the construction of the theory.

This simple theory of theories is false, for it assumes that theories contain empirical or observational concepts in addition to theoretical ones, whereas in fact empirical concepts occur only in the experimental protocols, and even there combined with theoretical concepts. Also, it is not true that deduction can perform the feat of taking us from the theoretical or abstract to the empirical or concrete. What is true is that the axioms of a theory are seldom independently testable because no axiom contains all the predicates necessary to identify a thing, state, or event. The postulates of a factual theory must be combined with one another, as well as enriched with additional hypotheses, data and indicator hypotheses, to yield predictions concerning specific things in specific states. In short, we must inject some empirical content into a theory if we wish the theory to face experience: by itself it has none.

To conclude, indicator hypotheses are indispensable to test hypotheses and theories. But many indicators used in ordinary life cannot be employed in science or technology because they are ambiguous, imprecise, or both. Not all laughter indicates joy, and not every fluctuation in the Dow-Jones index represents a real change in the economy. The search for reliable indicators is a task both theoretical and empirical. The first because only a theory can tell us whether a given sign does in fact point to a certain unobservable rather than another, by disclosing the objective link between observable and unobservable. And only empirical checks can validate an operationalization procedure, for it involves hypotheses.

3. DATA

3.1. *Measurement*

We need objective and precise information about the world, i.e. accurate data, for a number of purposes: to conduct the business of daily life, plan our activities, check our hypotheses and theories, and to explain and predict with the help of the latter. There are two main ways of learning data: producing them oneself or borrowing them from others. And there are three modes of generating data: by observation, measurement, and experiment. Observation, whether direct of with the help of instruments and theories, is deliberate and controlled perception, and it is the basic mode of data generation. We studied it in Ch. 4, Section 2. We shall now examine measurement, which may be characterized as quantitative observation, or the observation of quantitative properties. Experiment, or the observation (and possibly measurement) of changes under our partial control, will be tackled in the next subsection.

All organisms, even unicellular ones, have sensors capable of detecting and even gauging certain changes, in particular gradients and deviations from the optimal values of certain parameters, such as temperature, salinity, and acidity. But only man has invented and constructed, over the past few millennia, a variety of measuring instruments of varying precision. The differences between these and the natural "measuring" devices are as follows: (*a*) every measurement proper presupposes the conceptual operation of quantitation, or assignment of numbers to the degrees of a property—e.g. the conversion of separation into distance; (*b*) some measurements presuppose also the construction of indicator hypotheses—e.g. that the angular velocity of the anemometer measures the speed of wind; (*c*) measuring instruments are equipped with pointers, digital dials, or some other indicators, as well as with scales, that allow one to "read" them; (*d*) the measuring instruments are detachable, they can be exchanged for others, repaired, and improved on. We studied quantitation in Ch. 5, Section 3.2, and indicators in the last section. We shall not study measuring instruments, the subject of instrumentation (see, e.g. Stein, 1965); instead we shall discuss some of the methodological and philosophical issues raised by measurement.

The very first such problem is: *What is measurable*? The usual answer is that facts are measurable for, according to a well-known formula, measuring is "pinning numbers on facts" (S. S. Stevens). What kinds of facts? Surely not things but their properties and changes thereof. And which ones? Obviously only the ones that can be manifested objectively—e.g. generous actions but not (so far) generous feelings or intentions; and prices but not values (in use). Clearly, but what is a measurable property? The short answer is this: A property is *measurable in principle* iff it is (*a*) quantitative (i.e. the corresponding concept has been quantitated) and (*b*) either manifest (observable) or lawfully related (through an indicator hypothesis) to a manifest property. Whether a property is actually measurable at a given time depends on the state of the art, opportunity, and resources.

The two measurability conditions above, (*a*) and (*b*), can be summed up in the phrase 'theory dependence'. This dependence is denied by empiricism, according to which measurement data belong to the theory-free "empirical basis" of knowledge. Experimentalists know better: they know that the very design and operation of measurement instruments depends on theories. For example Rutherford, perhaps the greatest experimentalist in our century, organized as follows the first part of his classic treatise *Radio-Activity* (1904). He devoted the first chapter to a qualitative description of radioactive substances, the second to the *theory* of ionization of gases, and the third to measurement methods (some of which use that theory, and others different theories). This was necessary to explain why the discharge of charged bodies is a reliable indicator of the presence of a radioactive substance (the radiation of which ionizes the surrounding air). In the absence of some well-confirmed theory one may "pin numbers on facts" without understanding what one is measuring. IQ measurement is a case in point: it is not based on theory and it can be put to evil uses. (See Gould, 1981.)

If a theory states that objects of kind K have property P, then the experimenter may decide to devise a procedure for measuring P. (For example, unlike action at a distance theories, the electromagnetic field theories prompted experimentalists to produce and detect electromagnetic waves, and to measure their properties, such as wavelength and frequency.) If the experimentalist fails to detect the theoretically predicted property, then either the theory is at fault or his experimental design is inadequate. Should the theory be successful in a number of other cases, the latter inference is in order, and alternative experimental designs ought to be tried. If on the other hand a successful theory does not state that the objects of kind K have property P, then if the theory is true, P must be regarded as unmeasurable, perhaps because nonexistent.

For example, according to quantum mechanics the three components of the spin of a particle cannot all be measured at the same time. (This is how the noncommutativity among the spin components is usually interpreted. In my own interpretation unmeasurability derives from nonexistence: if one of the spin components is "well defined", i.e. has a sharp value, then the other two are not.) On the other hand, according to a classical or semiclassical theory, where the spin and other dynamical variables are "hidden" (i.e. scatter-free) variables, the particle would possess all three components at the same time, so they would be simultaneously measurable in principle. In short, measurability is critically dependent upon theory.

The central philosophical and methodological question about measurement is of course: What is it? The short answer is poetic rather than technical: Measurement is a synthesis of fact, reason, and action. Let us spell this out. (See Pfanzagl (1959) and Bunge (1967b) for different versions.) Consider a thing possessing a property P that comes in degrees, and call $\mathscr{P} = \langle P, \lesssim \rangle$ the relational system formed by the set of such degrees together with its intrinsic factual order $\lesssim$ (e.g. weaker than or as strong as). Conceptualize $\mathscr{P}$ by constructing a magnitude the values of which are, in the simplest case, real numbers together with units—e.g. 7 cm $\sec^{-1}$—and call $\mathscr{R} = \langle R, \leq \rangle$ the set of such values together with its order $\leq$.

Quantitation (or numerical quantification) is a mapping of $\mathscr{P}$ into $\mathscr{R}$ preserving (representing) the objective order of $\mathscr{P}$.

Look now at the set M of marks on a meter designed to measure the given property via some indicator hypothesis—e.g. in such a manner that *weaker* corresponds to *to the left of.* Call $\mathscr{M} = \langle M, \lesssim \rangle$ the new factual relational system, where now $\lesssim$ is the conventional order of the marks. The measuring device involves a one to one correspondence between $\mathscr{P}$ and $\mathscr{M}$, and between $\mathscr{M}$ and some subset Q of the rational numbers (fractions) together with the same units as before. Some of the latter numbers will be represented on the dial of the meter. Call $\mathscr{Q} = \langle Q, \leq \rangle$ the conceptual relational system formed by such numbers (together with the appropriate units) in their natural order.

Altogether we have two *factual* relational systems, $\mathscr{P}$ and $\mathscr{M}$, and two *conceptual* ones, $\mathscr{R}$ and $\mathscr{Q}$: see Figure 11.5. These four systems are related as shown in the following diagram:

$$\begin{tikzcd}
\langle P, \lesssim \rangle \arrow[r, "Quantitation"] \arrow[d, "Indication"'] \arrow[dr, "Measurement" description] & \langle R, \leq \rangle \arrow[d, "Inclusion"] \\
\langle M, \lesssim \rangle \arrow[r, "Scaling"'] & \langle Q, \leq \rangle
\end{tikzcd}$$

This diagram answers our question, albeit in a somewhat crytic manner, *viz*: Measurement is the empirical operation that maps some of the objective degrees of a property into rational numbers (together with the appropriate units) via indication and scaling.

Fig. 11.5. Measurement as a one to one correspondence between the objective degrees of a property and instrument readings. Modified from Bunge (1967b, p. 221).

What is being measured depends not only on the object of measurement but also on the measurement technique, which includes instrument design. Two or more techniques may or may not measure the same magnitude, and it is only when they do that we must require that the result obtained with their help exhibit a strong correlation. The case of speed measurement should make this point clear. An observer riding a train has at least three different methods of measuring the train speed, each of which yields values of a different function (Lévy-Leblond, 1980). First there is the external procedure: the observer counts the mileposts placed regularly along the track, and reads the times shown by the clocks in the railway stations. He thus obtains a value of the *velocity* or rather its average. Secondly, there is the mixed procedure: the observer still counts milestones but measures time on his own watch. What he measures now is a different property, namely *celerity*. A third procedure is purely internal, namely to employ an accelerometer and plot its values against the proper time of his watch. This allows him to measure the train's *rapidity*. For slow motions the values of all three functions are the same, but for fast ones they are very different. To take a simpler example, each aspect of aphasia is studied by a different method even though they are all grouped under the same heading. Thus the sodium amytal procedure tests speech, the tachistoscopic one reading, and the dichotic measure listening (Herron *et al.*, 1979). More on measurement techniques, in particular instrument design, in Bunge (1967b, Ch. 13, Section 13.5).

The point of the above examples was to stress the platitude that different measurement techniques *may* measure different properties. Operationism has stretched this point claiming that different measurement procedures *always* "define" different concepts (Bridgman, 1927)—even if the theory does not make such distinction. (A classical example, still found in books, is the pseudodistinction between inertial and gravitational mass. For a criticism see Bunge (1967c).) But of course only theories can draw conceptual distinctions; and if a theory states that two allegedly different concepts are one, then different measurement methods can only give (different or equal) values of one and the same property.

Measurement, then, does not define concepts, let alone things. Instead, it helps us find out some of the properties of things and in this way identify them correctly or control them efficiently. For example, there are alternative procedures for identifying acids, the litmus paper technique being the most popular. Each such procedure can be summarized into an operational *criterion* (not definition), such as "Anything that turns litmus paper red is an acid". Unlike a definition, such a criterion tells us not what an acid *is* but how to *recognize* it. Therefore operational criteria cannot replace theory; moreover they can be justified only by theory. Of course, in turn theories must be justified with the help of empirical operations, in particular measurements. So, we have a feedback loop or virtuous circle: "There is no measurement without theory and there is no theory without measurement" (Stein, 1965, p. 5).

What holds for properties holds also, a fortiori, for their lawful relations: an effort should always be made to try and check the latter by alternative methods for measuring the same properties, even at the risk of incurring the disapproval of short-sighted administrators who may regard such checking operations as wasteful. A strict operationist might object that different methods bring about different relations among properties, i.e. different laws. This claim has actually been made with regard to the psychophysical law relating the sensation intensity to the stimulus intensity (Wasserman *et al.*, 1979). What may have happened in this case is that differences in method elicit differences in the internal states of the experimental subject, which states are ignored by the law in question. This is the rule rather than the exception. If method 1 allows one to check the functional relation "$y = f_1(x)$", and method 2 "awakens" a second independent variable z and establishes the relation "$y = f_2(x, z)$", then the experimenter is likely to rejoice for having discovered a more inclusive relation. And he will be even more satisfied if he succeeds in showing that, upon "freezing" z (or restricting z to varying within a narrow interval), f_2 comes close to f_1, which is then shown to be but a first approximation to f_2.

A related philosophical problem is whether all measurement creates its object or at least interferes with it and whether, when it does, such interference can be corrected. A measurement technique is said to be *obtrusive* if it changes in any way the state (and a fortiori the kind) of the object of measurement, and *unobtrusive* otherwise. *Example 1*: A current or voltage measurement is slightly obtrusive, for it involves dissipating a fraction of the energy in the meter. But this effect can be corrected for with help of a second measurement, so the net effect is negligible. *Example 2*: Measuring the age of a fossil using the carbon 14 dating technique is highly obtrusive, for it requires burning the object. But alternative dating techniques have been invented which are far less obtrusive. *Example 3*: All interviews and questionnaires used by social scientists and psychologists are somewhat obtrusive, for people change their behavior when they know that they are being observed. Think of questions such as "How often do you batter your children?", "Are you the kind of people who help their neighbor in need?", and "Do you sympathize with communism?"

There is no question but that, the deeper and more accurate a measurement technique, the more obtrusive it is likely to be. However, the history of instrumentation shows that, if we try hard, we are likely to invent means to minimize the effect of the observer's interference or at least to calculate its effect. For example, by lowering the temperature to near the absolute zero, thermal noise is eliminated, and magnetic fields are kept out of metals; and, by using semitransparent mirrors and hidden cameras, the experimental subjects cease to act in a self-conscious or in a hypocritical manner.

Still, there is one important case where it would seem that obtrusiveness is here to stay, namely in the measurement of properties of microthings. For example, if the position of an electron is measured with great accuracy, then—according to the Heisenberg inequalities—it is impossible to measure its velocity at the same time. However, these formulas can be interpreted in several ways (Bunge, 1977c). According to the popular interpretation, the measuring device disturbs the electron in an unpredictable way, imparting it an uncontrollable momentum: this is the *causal* intepretation, which ill accords with the stochastic nature of quantum mechanics. The Copenhagen interpretation avoids causality but introduces a subjectivity alien to the scientific approach: it states that the electron *has* no properties as long as these are not measured, and acquires them the way the experimenter wants.

The realist interpretation is that, in general, the electron *has* neither a sharp position nor a sharp momentum but only distributions of both, as well as the possibility of *acquiring* either a sharp position or a sharp momentum, but not both at the same time, under suitable environmental conditions. The electron position *becomes* measurable only if the electron is forced, by appropriate natural or artificial means, to adopt a state characterized by such property—which it will do only at the price of losing whatever sharp velocity value it may have had before. And if we decide instead to measure the electron velocity we must start by preparing the electron in a state characterized by a sharp velocity value rather than by a whole range of velocities. We cannot measure a property that the electron does not possess to begin with. There is nothing subjective about all this, for the conditions under which an electron gets its position (or velocity) sharpened may be natural or artificial. And, contrary to popular wisdom, the Heisenberg inequalities do not impose any limitations upon our knowledge: they only show that microthings are not particles. (But we should have known this ever since classical mechanics was shown inadequate to describe, explain and predict their behavior.) In short, we certainly alter the state of a microthing when measuring some of its properties, but we do not thereby create the thing at our whim and in violation of the laws of nature. When an experimenter undertakes to measure a property on an object he assumes the objective existence of some objects possessing certain properties and laws.

Still, it might be thought that, since natural things do not come with numbers indicating the values of their properties, the outcomes of measurement are wholly man-made. After all, by shifting the zero of a scale or adopting a different unit we may assign a thing any size or age. Likewise empty space is devoid of milestones, so why not think that it is metrically amorphous, hence that our assigning it metrical properties is purely conventional? The answers to these conventionalist innuendos are as follows. First, the pinning down of numbers on properties is basically no different from our constructing theories about things. Surely Maxwell's equations are not written on the electromagnetic waves that illumine this book, but those equations do fit them quite well. Second, we often handle, and in principle could always deal with, ratios—e.g. relative concentrations, densities, and the like—rather than with absolute quantities, and such ratios are unit-free, hence independent of any unit conventions. Thirdly, although the choice of scale (in particular zero and unit) is conventional, such choice, when adhered to consistently, renders intersubjective comparison and communication possible. Language too is largely conventional, yet such conventions are necessary for communication.

Units occur explicitly in the very formation of dimensional magnitudes such as permeability and productivity. (Cf. Ch. 9, Section 3.1.) All scientists are familiar with the rules for the formation of such concepts, and will reject as ill formed an expression such as 'The mass of body *b* equals number *c*', admitting instead expressions of the form 'The mass of body *b* equals *c* grams', or 'The mass of *b* in grams equals *c*'. (The classical mass concept is formalized as a function from pairs $\langle$body, mass unit$\rangle$ to positive numbers.) Units are defined in conceptual terms, preferably in terms of law statements. For example the newton, a force unit, is defined via Newton's second law of motion. (One newton is the force that causes an acceleration of one meter per second per second to a body possessing a mass of one kilogram.)

In addition to units we need standards for some of them, i.e. their materializations. Such standards are carefully described physical things or processes that can be easily replicated or reproduced as well as improved on. Thus the length standard used to be a meter long platinum bar under certain pressure and temperature conditions. As from 1983 the meter standard is the distance light travels in vacuum in a given fraction of a second. (The speed of light is taken as a base line equal to 299,792,458 m/sec.) Contrary to careless textbook affirmations, standards do not *define* units but *materialize* them. And, unlike units, which are arbitrary, standards are chosen for their stability and reproducibility. Entire governmental laboratories, such as the US Bureau of Standards, are devoted to keeping and replicating standards as well as to investigating ways to improve on them.

Needless to say, improvements in standards and, in general, in instrumentation, require imagination and motivation allied to familiarity with basic theory, electronics, and occasionally also computer programming. Improvements in instrumentation over the past few decades have often advanced at the rate of one order of magnitude (i.e. a factor of 10) every 5 years or so. Fewer and fewer institutions can afford to keep this pace. Hence, unless something drastic be done, experimental research will soon become the privilege of a few giant industrial laboratories—which are not interested in basic research anyway. There is then as much to bemoan as to celebrate in the swift progress of instrumentation.

In addition to favoring an excessive concentration of human and material resources in a few rich laboratories, quick progress in instrumentation may have the following negative side effects: (*a*) an accumulation of detail may make us forget the whole; (*b*) observation, measurement and computation, which are only means, may be turned into ends, and correspondingly scientists into technicians; (*c*) alternative approaches, requiring more modest laboratory equipment, tend to be ignored as the value of research projects tends to be gauged by their cost; (*d*) when too much reliance is placed on instruments, basic questions are hardly asked, and ambitious theories hardly sought. Austerity has its virtues: as Lord Rutherford used to say, "We've got no money, so we've got to think."

Suppose now that all the preliminary conceptual operations have been performed: we have constructed or adopted the magnitude (quantitative attribute) to be measured, and if necessary also its hypothetical (though reasonably well confirmed) relation to an accessible property (indicator).

Moreover we have designed our equipment with the help of a bunch of law statements, and have checked and calibrated it, so that it is ready to measure, to within an acceptable error, what we want to measure. Moreover, suppose we have obtained a suitable preparation—crystal, insect, or what have you—known or suspected to possess the property of interest. (This is no mean task, for we want a specimen or a sample representative of the original population, relatively easy to study, and we wish to minimize any destructive interference with it.) Only now are we ready to perform the measurements and record them, or perhaps to entrust them to a computer-assisted device. Quite frequently, whereas this last stage may be completed in a matter of days, the previous stage may consume months or even years of work sometimes involving dozens of coworkers and technicians.

We now have a set of raw data. They are not sacrosanct: they must be screened, for some of them may be far too weak signals and others plain errors. The remaining data are corrected in some way or other—e.g. reduced to standard atmospheric pressure and temperature. Even this data reduction may be insufficient: usually we want to extract from them some characteristics representing them as a whole, such as the average and the scatter around it (i.e. the standard deviation). The latter may be taken as a good measure of the measurement error. Such error is not necessarily a mistake on our part. Sometimes it exhibits the spontaneous random (e.g. thermal) changes of both object and apparatus. (It can be considerably decreased by working at very low temperatures.) At other times the statistical scatter exhibits the variety of the individuals composing the sample under investigation. (In sum, σ is an ambiguous indicator.) In any case, the correct summary of a run of measurement reads thus: The average value plus or minus one standard deviation.

The calculated average is usually called the "real" or "true" value of the property of interest although actually every one of the values that goes into the calculation is real. Ideally we should keep them all, or at least we should not throw away all of them unless we can make sure that the sample under study is rather homogeneous in the respect of interest. See Figure 11.6 for a case of hasty throwing away of valuable information. In any event, the results of measurements are "cooked" before being compared with those of other runs or with theoretical values. Mathematical statistics and the theory of errors of observation study such data "cooking" procedures and pose a number of genuine and interesting methodological problems that are still awaiting philosophical analysis. Suffice it to mention the ground, or

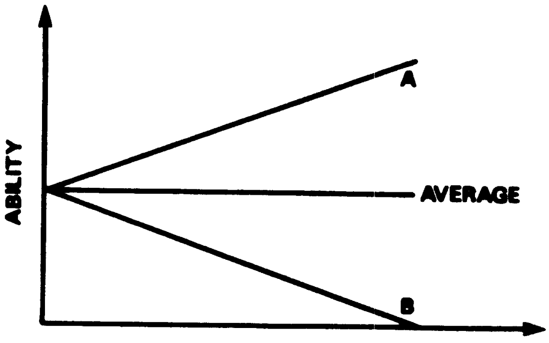

Fig. 11.6. A group of experimental animals is tested for some ability and its variation in the course of time. Those of kind *A* increased their ability while those of kind *B* decreased it. The average showed no change, so if it had been taken as a faithful representative of the group it would be uniformative. Adapted from R. M. Yerkes (1907) *The Dancing Mouse*, p. 273. *New York: Macmillan.*

lack of it, for adopting averages as the real or true values, and for discarding outlying values (i.e. measurement results departing from the average by more than three standard deviations).

We close this section with some remarks on two supposedly extremely general theories of measurement. One of them is what mathematical psychologists call *measurement theory* (e.g. Stevens, 1951; Suppes and Zinnes, 1963), and which others would call 'formation and analysis of scientific (in particular quantitative) concepts'. In fact this theory is unconcerned with the empirical operations everyone else calls 'measurements'—such as the actual determination of durations and electric charges—and deals instead with what it calls 'measurement scales', and the adult sciences call 'quantities' or 'magnitudes'. The theory contains basic mistakes that render it useless. One of them is that it ignores dimensional analysis and even the very notion of a dimension. Another is that it does not contain a proper account of units. (For algebraic theories of dimensions and units see Bunge (1971).) A third is that it ignores intensive quantities, such as density and *per capita* income, which are often primitive in scientific theory. A fourth is that is postulates that all extensive magnitudes (such as length) are additive, whereas in fact some of them, such as mass and entropy, are subadditive. (I.e. the mass of a system is somewhat smaller than the sum of the masses of its components.) The moral is plain: It is not advisable to try and build general theories of scientific concepts with disregard for the factual theories that house such concepts. (For details see Bunge (1973c).)

Another purportedly general theory of measurement is the *quantum* *theory of measurement* or, rather, the family of theories dealing with measurement in general on the basis of quantum mechanics. The aim of such theories is to analyze micro–macro interactions, in particular those between a microthing (e.g. an electron) and a measuring apparatus. Whereas some such theories are strictly physical or objective, others make room for the observer's mind (without however containing a single variable representing mental functions). The main trouble with all these theories is that they are nothing but academic exercises consisting in applying quantum mechanics to extremely idealized situations: they ignore that every actual measurement measures one or more *particular* properties on *specific* things with the help of *special* devices.

There is no such thing as the all-purpose measuring instrument imagined in those theories. Since every type of measuring instrument is quite specific, it requires its own theory, which is usually a classical one and occasionally a mixture of classical and quantum theories. (Think of the enormous difference between optical spectrographs and mass spectrographs, or between thermocouples and scintillation counters.) A general theory of measurement may explain some features of measurement, such as its irreversibility and amplification. But, because of its generality, it can issue no precise predictions and, not being predictive, it is empirically untestable. For this reason none of the many general quantum theories of measurement can ever be checked experimentally. So, the choice among them is a matter of indifference: one may choose either of them or be more parsimonious and ignore them all. On the other hand it is legitimate to try and unravel the main features of measurement and even to build a general theory of experiment involving no particular laws and therefore having no predictive power at all: See Appendix 5.

3.2. *Experiment*

Like measurement and unlike mere perception, experiment is active experience and one blended with reasoning. And, like measurement, experiment can find new facts or test hypotheses. However, experiment can find facts that measurement cannot unless it is part of experiment—namely facts that occur because of the deliberate alteration of the object of study. Indeed a fact finding experiment helps solve problems of the form "What happens to X if Y is done to X?"—e.g. what happens to a frog upon the unilateral destruction of its labyrinth, or to a community deprived of its leadership? Experiments of this kind are more difficult to perform than experiments aiming at testing hypotheses of the form "If Y is done to X, then Z results", for in this case the hypothesis itself directs us to look for effects of kind Z when controlling variable Y, whereas in the former case we must look for every possible difference that Y may make.

Unlike measurement of the unobtrusive kind, every experiment involves controlled changes in the object of study. Indeed an experiment may be defined as a controlled action performed by an animal on some other object, or on a part of itself, with the aim of solving some problem—cognitive or practical—concerning the object of experimentation, and such that the animal is able to receive, record, and analyze the reaction of the object to that action. What is typical of all experiment, in contrast to observation, is that the experimenter controls the object and its environment. In some cases this control is limited, i.e. restricted to the properties thought to be of interest. But in others the control is nearly total, for it includes the production of the thing or event of interest—as is the case with experiments with particle accelerators, with the artificial assembly of macromolecules such as genes, and with experimental social groups.

More precisely, an *experimental device* (or *set up*) is a concrete (material) system with at least three components: the object w of study (which can be replaced from one experiment to the next), an object supplying a stimulus (input) of some kind to w, and an object measuring the response (output) of w to that stimulus. An *experiment* on w consists in (*a*) subjecting w to a stimulus and observing its response; (*b*) observing the output of the same object w or one of the same kind when not subjected to the given stimulus, and (*c*) comparing the responses and finding out whether the difference between them is significant, i.e. due to the stimulus rather than attributable to chance or to idiosyncrasies of the object of study.

Needless to say, the choice of object and stimulus, as well as the design of the set up, in particular measuring device, are guided by hypotheses; and the final comparison (allowing one to draw "conclusions" about the effect of the stimulus) is controlled by statistics. The net outcome of an experiment is summarized in a set of statements, tables, or figures called the experimental *finding*. Sometimes nothing is found except that the experiment yields no evidence for a given hypothesis—e.g. that there are freely roaming spirits. Papers reporting on such "negative" results are regularly published in the scientific literature—seldom in the pseudoscientific (e.g. parapsychological or psychoanalytic) journals.

The advantage of experiment over observation and even measurement is best appreciated by studying some cases. *Example 1*: To find out whether information can be transferred from one animal to another by surgical transplant, Lindauer and his coworkers (Martin *et al.*, 1978) proceeded as follows. A collection of honeybees was divided into two groups, the experimental or donor bees and the recipient ones. The donor animals were fed between 10 a.m. and 12 a.m. for six days in a row, whereas the recipient bees were fed either continuously or a variable times, so that they did not learn any feeding pattern. The mushroom bodies (one on each side of the brain) of the donor bees were then transplanted into the ignorant bees. It was found that after 3 or 4 days the recipient bees behaved like the "learned" ones. The conclusion was that some information gets "engrammed" into the brain, and can be transferred by surgical transplant. *Example 2*: To test the hypothesis that speech in right-handed persons is a function of the left cerebral hemisphere alone, Kinsbourne (1971) performed the following experiment. Three right-handed men who had suffered left hemisphere strokes causing aphasia were given injections of amytal, first in the left carotid, then in the right one. The former had no effect, whereas the injections in the right carotid arrested completely what little speech the patients had been left with. The conclusion was that the right ("minor") hemisphere does participate in speech production. *Example3*: To check the hypothesis of the genetic origin of intelligence (held by A. R. Jensen, R. J. Herrenstein, H. J. Eysenck, and others), Schiff *et al.* (1978) compared the school performance of middle-class children with that of working-class children adopted by middle-class families. (Theirs was an *ex post facto* experiment: the foster children were unwitting experimental subjects.) They found that the children perform in school according to their homes, not their genetic origin: i.e. what counts most for learning are the cultural, not the biological parents.

We are so used to the idea that experiment is a necessary component of science and technology that we tend to forget how recent it is, and take it naively for granted that every widely advertised theory, artifact, or procedure, has passed suitable experimental checks. Experiment, as distinct from intuitive trial, was introduced only in the 17th century. Even in the next century physicists made few experiments; most of the empirical support for the new mechanics came from astronomy. Until the end of the 19th century mechanics was regarded as a branch of mathematics, not of physics. Biological experimentation was not conducted systematically until about 1850. Although medicine is supposed to be experimental, the first experiment to determine the efficiency of surgery to deal with breast cancer was not performed until 1981. The first laboratory of experimental psychology was inaugurated in 1879. Even though psychiatry is supposed to be a branch of medicine, the proposal in 1980 by a committee of the U.S. Congress to investigate experimentally the efficacy of psychotherapy raised an outcry among clinical psychologists and psychoanalysts. The very idea of a social experiment is foreign to most people. Very few have heard about the New Jersey negative income tax experiment (1968–1972). And many scientists still have hazy ideas about key features of experimentation. Thus some (e.g. Abraham and Marsden, 1978) regard computer simulation—a valuable auxiliary to actual experiment but no substitute for it—as experimentation. Others believe that any sample, regardless of size and mode of obtainment, will do; and still others commit the gambler's fallacy, believing, e.g. that the sequence HTHTHT of coin tossings is more probable than HHHHHH (Tverksy and Kahneman, 1971). All of which goes to show that insufficient attention is being paid to the methodology of experiment and, in particular, to its conceptual basis.

The design and interpretation of every experiment presuppose a number of hypotheses, most of which are rarely if ever noted, partly because few philosophers have ever analyzed any experiments. The presuppositions of experiment can be grouped into *generic* (shared by all experiments) and *specific* (characteristic of every type of experiment). See Figure 11.7. The generic presuppositions are in turn of two kinds: philosophical and

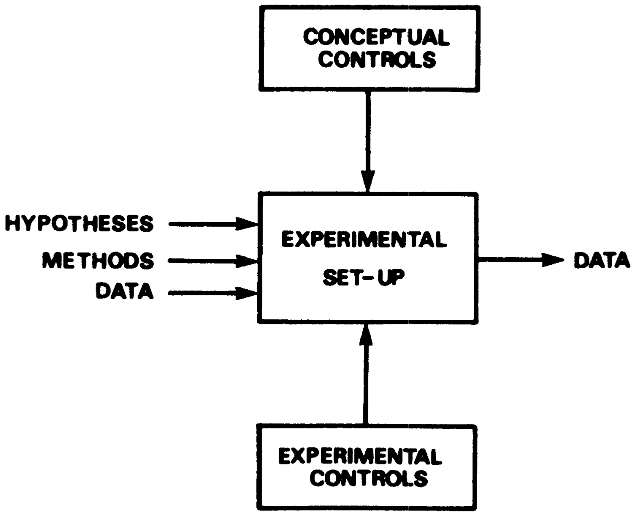

Fig. 11.7. A well-designed experiment has conceptual controls (in particular statistical ones) as well as experimental ones (e.g. of temperature and inflow of air). And in the design and interpretation of the experiment not only data and methods but also hypotheses (philosophical, statistical and scientific) take part.

statistical; and the specific ones consist in particular hypotheses or theories about the nature and behavior of the objects of experiment or the experimental means. Let us examine them quickly.

The main *philosophical* presuppositions of all experiment are these:

(*a*) *Reality*: The members of the experimental and control group, as well as the measuring instruments, exist really although some of the hypothesized objects may be imaginary. (If all the things involved in an experiment were figments of our imagination, then imaginary experiments would suffice.)

(*b*) *Lawfulness*: All the objects involved in the experiment behave lawfully. (There would be no point in performing experiments if nature or society were to give significantly different "answers" every time we pose them the same "question".)

(*c*) *Causality*: All the things involved in the experiment satisfy some form of the causal principle, however weak, e.g. "Every event is the effect (with some probability) of some other event". (Otherwise no deliberate production of an effect and no effective control of variables would be possible.)

(*d*) *Randomness*: All the variables involved in the experiment are subject to some random fluctuation, both intrinsic and due to external perturbations. (Otherwise we would not be able to explain the statistical scatter of results.)

(*e*) *Insulation*: Objects other than the object of the experiment, the experimenter, and his experimental means, can be neutralized or at least monitored for the duration of the experiment. (Otherwise no significant changes could be attributed exclusively to changes in the control variables.)

(*f*) *Disturbances or artifacts*: It is always possible to correct to some extent, either empirically or theoretically, for the "artifacts", disturbances or contaminations caused by the experimental procedures. These are not the deliberate alterations of the object but the unwanted distortions of it or of its image—e.g. the colors and diffuse rings produced by optical lenses, the solvents that change the reactivity of reactants, and the stains that impregnate living tissues with metals. (If such partial corrections were impossible we could not legitimately claim that the thing for us—as it appears to us—resembles closely the thing in itself—such as it is when not subjected to experiment.)

(*g*) *No psi*: It is always possible to design experiments in a manner such that the experimenter's mental processes exert no direct influence on the outcome of the experiment. I.e. the experimenter can be shielded or uncoupled from the experimental set up, so that his bodily and in particular brain processes do not alter the experimental results. Servomechanisms are particularly useful to this end. (Otherwise the outcome of the experiment could be produced at the experimenter's whim, and the experimenter would be testing nothing but his own mental, e.g. psychokinetic, abilities.)

(*h*) *Explicability*: It is always possible to justify (explain), at least in outline, how the experimental set up works, i.e. what it does. I.e. it is possible to form a conceptual model of the experimental device using well confirmed hypotheses and data. (Otherwise we would be unable to draw any conclusions.)

In addition to the foregoing philosophical principles, the following *statistical* principles and rules are supposed to be observed in every experiment, particularly in the biological and social sciences:

(*a*) The objects of experiment should be drawn from as *homogeneous* a population as possible. To this end the original population, if extremely heterogeneous, should be partitioned into equivalence classes. (Otherwise no general patterns may be recognized and correspondingly no generalizations may be conjectured.)

(*b*) When the total population is practically inaccessible (e.g. for being too large), a sample is to be drawn from it in such a way that it be *representative* of the former. Mathematical statistics has come up with techniques for maximizing representativity.

(*c*) The sample to be experimented with should be divided into two roughly equal parts: the *experimental* group (the members of which will be subjected to the given stimuli) and the *control*. The assignment to each group should be done in a random manner, in order to minimize bias in the choice of experimental subjects as well as placebo effects and last, but not least, in order to be able to apply probability ideas. (No randomness, no probability.)

(*d*) Experiments with human subjects should be *double blind* in order to avoid the placebo effect: i.e. neither the subject nor the experimenter should know who gets what. This information should be reserved to technicians or computers and utilized only once all the results of the experiment are in.

(*e*) The experimental design should be *checked* for possible systematic errors (or errors in design), and the accidental (random) errors should be calculated and noted.

(*f*) The *significance* in the differences of behavior between the experimental and the control group should be evaluated with the help of some significance test (e.g. chi-square).

(*g*) The experiment should be evaluated, and if possible repeated, by *independent* groups—not to forestall deception but to correct possible systematic errors.

This incomplete list should suffice to show that, contrary to widespread opinion, statistics should not enter only at the very end, to "process the data", but should be involved throughout the experiment, from design to evaluation. The regulative function of statistics is particularly apparent when the data arrive sequentially rather than in whole batches. In the first case the experimenter can stop gathering or producing data but must do so according to definite rules, for otherwise he may commit the fallacy of optimal stopping, or terminating the experiment as soon as his favorite hypothesis has been confirmed—a habitual tactics of parapsychologists. Such "stopping rules", or prescriptions for deciding when to stop gathering data, are fashioned by sequential statistical analysis.

Some of the above-mentioned statistical safeguards can be ignored in physics and chemistry, which usually work with extremely homogeneous populations (e.g. rather pure chemicals). But the biological and social sciences, which deal with complex systems characterized by an enormous individual variability, cannot ignore them. Yet, although those principles have been taught in standard courses over the past half century, they are still often ignored. *Example 1*: Until very recently studies of mental development and of neurophysiological "correlates" of learning were conducted without adequate controls and sometimes with no controls at all (Denenberg, 1979; Thompson *et al.*, 1972). *Example 2*: Experiments in psychoanalysis are conspicuous by their absence, and in parapsychology notorious for inadequate controls and for a fanciful use of probabilistic and statistical ideas. (Cf. Hansel, 1980; Alcock, 1981.) *Example 3*: The most famous of all experiments in human engineering since the days of Taylor was the Hawthorn experiment (1927–1933) on the effect of human relations on productivity. Its analysis half a century later (Franke and Kaul, 1978) has revealed that it had not been an experiment proper because no control groups had been involved, so that the inferences had been of the *post hoc propter hoc* type. Second, the data were not subject to statistical analysis. Third, between the start and the termination of the "experiment" the Great Depression set in, introducing a major variable which the investigators were not in a position to control, namely the fear of unemployment and the corresponding toughening of management. Fourth, fatigue was reduced by working fewer hours a week.

Finally we come to the *scientific* hypotheses underlying the design, performance, and interpretation of experiments. These hypotheses are of two kinds: whereas some of them refer to the means (in particular the measuring instruments), others concern the objects of experiment and their interaction with the former. We examined the hypotheses of the first type in the preceding section; let us now look into those of the second type. At first sight no such hypotheses are involved in experiments attempting to answer questions of the form "What happens if *X* is done to *Y*?" A closer examination reveals that, far from choosing the stimulus *X* at random, the experimenter is guided by both his information, however scanty, about *X* and *Y* and some hunches, however vague, on the possible effects of *X* on *Y*. Otherwise he would succeed only by sheer luck, for experimenters do not have an infinite time and things are not susceptible to all possible stimuli. (Try to play Beethoven to a fly. Rock music, on the other hand, might have some damaging effect.)

Every well-designed experiment is inspired or misguided by some specific hypothesis or other. For example, an experiment inspired in stimulus–response psychology controls only behavioral variables. Hence it can draw valid conclusions only if the experimenter has "frozen" (kept constant) all the relevant internal variables, such as drives and motivations. (For example, it has been reported that rats prefer complicated roads leading to food sources, to straight ones. Maybe so, but any experiment to test such curiosity or adventurousness is worthless unless it has been ascertained that both the curious and the greedy rats are equally hungry.) On the other hand an experiment in physiological psychology will control physiological as well as behavioral variables. For example, to find out whether neural system *X* is "involved" in (or "mediates") behavior *Y*, block or stimulate the activity of *X*, and watch for behavior of kind *Y*. (*Dual*: Modify behavior from *Y* to *Z*, e.g. by placing constraints on motion or on perception, and watch for changes in the activity of neural system *X*.) Another example: it is usually assumed that it is possible to separate hereditary from environmental factors in the study of intelligence by using the twin method. (Each of the monozygotic twins is placed in a different environment, and their performance is compared.) This technique presupposes that one-egg twins are strictly identical, which in turn follows from the assumption that heredity is locked in the cellular nucleus. But Darlington (1970) refuted this latter hypothesis by finding extracellular DNA. Therefore one-egg twins, though possessing identical nuclear DNA, might differ in their non-nuclear DNA. If this difference proved to be significant, then the "identical" twins would not be strictly identical and the twin method would not be fully reliable. But this is still *sub-judice*.

Regardless of the reliability of the twin technique, the methodologically important point is that every experimental technique presupposes some hypotheses and so is just as fallible as these. (For the opposite view see, e.g. Bachrach (1962) or Rapp (1980).) In other words, experimental results are not more reliable or certain than the hypotheses underlying them, and they are not atheoretical anyway. (To be sure, the routine operations that can be performed by technicians once the original experiment has been designed do not require any knowledge of the hypotheses that went into the original experimental design. But this is beside the point: we are concerned with original research.)

Empiricism has extolled the value of the so-called *empirical basis* and its theory-free nature. There *is* no such pure theory-free empirical basis: every worthwhile experiment presupposes a number of hypotheses and, if conclusive, it confirms or undermines some hypotheses or calls for new ones. An experiment calls for a new hypothesis or theory if the existing ideas do not account for its outcome, i.e. do not explain satisfactorily how the experiment works or do not predict well its results. But of course no set of experimental results, no matter how numerous, precise and accurate, will suggest unambiguously a theory. For example, "Thousands of learning experiments with rats have not yielded a set of principles from which the performance of rats can be derived satisfactorily, although a great deal of progress has been made in the 75 years or so since the first rat was introduced into the first maze" (Bitterman, 1975).

Experiment is so essential to science and technology that it is sometimes believed to be all-important, and consequently laboratory work is regarded as a goal in itself. This is a one-sided view because it ignores the many hypotheses involved in every experiment, as well as the impact that experimental findings may have on existing hypotheses or on the construction of new ones. Like other methodological errors, this one has serious negative effects on inquiry. Here are some: (*a*) concentrating interest on variables, details, or components that are easily controllable or measurable; (*b*) focusing on instruments and techniques (e.g. electron microscopy and electrophysiology) to the detriment of the object of study; (*c*) neglecting naturalistic situations and disregarding the environment (particularly in genetics and psychology) as well as experimental "artifacts"; (*d*) underrating theory—which suggests, guides, explains, and often replaces experiment; (*e*) adopting an anthropomorphic view according to which no event happens, or at least matters, unless it is elicited and measured by some experimentalist (as is the case with the Copenhagen interpretation of quantum mechanics). Such negative effects of the exclusive concentration on laboratory work are visible in all the sciences, particularly the less developed natural sciences. The only effective antidote is a strong dose of a mixture of (good) theory and (good) philosophy.

Having warned against exaggerating the importance of experiment, let us now warn against any attempt at curtailing its scope. To be sure, some areas of inquiry are still closed to the experimental method—e.g. astrophysics and ethics. However, the experimental method has made decisive inroads in a number of areas that used to be regarded as impregnable to it. *Example 1*: Experimental astronomy started with the first Sputnik (1957). *Example 2*: Experimental geology, conducted on small scale models, has been in existence for decades. *Example 3*: Experimental palaeontology is on the way. Thus, by working on models of the dermal bony plates along the back and tail of *Stegosaurus*, it has confirmed the hypothesis that they served a thermoregulatory function (Farlow *et al.*, 1976). *Example 4*: Experimental archeology, more than a century old, has succeeded in explaining the use and efficiency of a number of artifacts and techniques, from food storage to earthwork to stone working and pottery manufacture (e.g. Coles, 1973). *Example 5*: Experimental sociology, tried sporadically and on a small scale several times during this century, was launched on a large scale in 1968 with the New Jersey income maintenance experiment. Moral: Never prophesy that a given field of factual inquiry will remain forever beyond experimental control.

4. CONCLUDING REMARKS

Whereas self-evidence is the gate to self-deception, hard evidence is the seal of adequacy—be this truth or efficiency. Evidence for or against data, hypotheses or theories, techniques, rules or plans, can be conceptual (in particular theoretical) or empirical. In other words, an idea is supported or undermined by other ideas or by empirical tests, from observation and measurement to experiment and action. And the evidence may be intradisciplinary or interdisciplinary (i.e. coming from another field of inquiry).

All empirical tests involve hypotheses and often call for further hypotheses or even entire theories. The hypotheses involved in the design and interpretation of tests are not always explicit: sometimes they are just biases. (Thus different field linguists studying the same population are bound to detect some different phonemes, because each expert expects certain sounds—which he duly records—while he does not expect others—which he may fail to record.) In science and technology there is no purely empirical basis on which to build theories, and no theories that could not possibly be affected, one way or another, by empirical tests. This is not to devaluate data but to remind ourselves that, unlike the anecdotal data of ordinary life, those of science and technology are "contaminated" by theory. Nor is it to revile speculation but to remind ourselves that all speculation must eventually be confronted with hard facts—for facts are, after all, the subject matter of science and technology.

Not all data are equally valid. In fact it has become customary, particularly in the social sciences, to class them into *hard*, *semihard*, and *soft*. Hard data are those provided by measurement or experiment on things of known composition or environment. In general they are repeatable (to within experimental error). Semihard data result from the observation of things of poorly known composition and environment. In general they are nonrepeatable. Statistical data, particularly in the social sciences, are of this kind. Finally, the soft data are occasional or anecdotal: they come from casual observation or hearsay, and they are nonrepeatable. In general, the more and better theory has gone into the production of a datum, the harder it is.

The above classification concerns the source or mode of production of data, not their intrinsic worth (truth and usefulness). In fact a hard datum can be false, or at least imprecise, or it can be useless. (This does not mean that there are no hard *facts*, but instead that our knowledge of them, even when obtained the hard way, may turn out to be false.) And although anecdotal data constitute no evidence, they are occasionally more valuable than many a trivial measurement or experimental result. For example, the observation of caged and free-roaming apes has triggered or supported much important scientific work in antropology, psychology and sociology. The quality of the data source (hard, semihard or soft) is important but not more so than the output: we judge the reliability of data sources by their performance, not conversely. (For the contrary thesis, that the plausibility of propositions depends upon the reliability of their sources, see Rescher (1976).)

The best data are those that constitute evidence for or against some hypothesis or theory and those which are precise, accurate, and varied. We will not insist on the importance of the theoretical relevance of data: suffice it to note that nobody collects data for their own sake, but always to some purpose, such as trying to discern a pattern or to check a hunch. As for repeatability, essential to minimize error, it is not always obtainable, particularly in the historical sciences. Variety, on the other hand, is in principle always obtainable because every property is lawfully related to some other properties. And it is desirable to minimize error. Thus palaeobiologists do not rely exclusively on fossils and the theory of evolution: they also make use of geological data and of information about living organisms.

The standards or criteria for evidence have become increasingly exacting in all fields of inquiry, from science and technology to the humanities and the law, since the beginning of the Modern Era. Thus hearsay and circumstantial evidence are no longer accepted, either in the laboratory or in the court of law, except as hints pointing to further search for solid evidence. Nor, of course, is a mere statement of belief or authority accepted: instead, evidence for truth or efficiency, as the case may be, is required. This dramatic progress in the standards of accuracy can be explained not only as an aspect of intellectual advancement but also by external motives. As science and technology increase in cultural and economic value, it becomes increasingly important to know to what extent they work and in which respects they are still deficient. And as the struggle for economic, political and cultural rights proceeds, the law is required to observe them more faithfully, to which end it must substitute objective evidence for denunciation and confession.

The data generated by observation, measurement or experiment may discharge several functions. They may pose problems and illustrate hypotheses. They may call for, and partially suggest, new hypotheses or theories. They may "activate" known hypotheses or theories by filling some blanks in them (i.e. assigning values to constants or parameters). Or the data may be used to assess the worth of our ideas: the truth of hypotheses and theories, the precision and accuracy of techniques and instruments, or the efficiency of rules, proposals, and artifacts. Let us study next the latter operation, namely evaluation.

CHAPTER 12

EVALUATING

All cognitive activities are motivated. We seek to find, think to solve problems, plan to attain goals, talk and listen to communicate, and so on. And we evaluate all the conscious activities, whether purely cognitive or using some knowledge. We evaluate problems and their solutions, propositions and proposals, theories and designs, methods and artifacts. We evaluate some of them for truth and others for usefulness: these are the supreme values in matters of cognition. Any other values, such as simplicity and beauty, are subsidiary with regard to knowledge. To be sure, a false hypothesis and a useless machine may be valuable in some regard—e.g. heuristically in the former case and commercially in the latter—but ultimately they are to be discarded.

Those two main values, truth and usefulness, are quite distinct: so much so that certain false propositions are valuable (for evil purposes) whereas some true ones have no practical use. This does not entail that truth and usefulness are always unrelated. Modern technology involves both, for it employs theories that have passed truth tests, and does so in order to guide the production or maintenance of (supposedly) useful things. What the distinction does entail is that truth is no substitute for usefulness or conversely, whence the search for truth is not the same as the search for usefulness. In particular, science is not identical with technology. In a way the latter is more demanding than the former, for it uses and produces both truth and usefulness.

Although truth and usefulness are the supreme values of cognition, they are quite elusive: they are difficult to define and recognize. To be sure, there are precise definitions of logical and mathematical truth, but they are inapplicable to factual propositions. And anyone can draw a list of useful items, but few can say what value is. We shall outline a program for a correspondence theory of truth, and another for a theory of value (Section 1.)

Being seldom manifest, truth and usefulness are often hard to pinpoint. As in the case of other unobservables, we need indicators. I submit that there are both empirical and conceptual indicators of truth and usefulness. The foremost empirical indicator of truth is confirmation, and that of usefulness efficiency (Section 2). And the main conceptual indicator of either is compatibility with our background knowledge (Section 3). We come up then with a battery of truth indicators and another of usefulness indicators. Each battery allows one to assign, at least temporarily, degrees of truth or of usefulness, as the case may be. I wrote 'assign' not 'disclose' or 'discover', because—and this is a central thesis of this chapter—neither truth nor usefulness are intrinsic and eternal properties: they are contextual and changeable. As von Uexküll (1928, p. 1) said, scientific truth is today's error, and the progress of science is a process of moving from gross to fine error. Likewise we may say that usefulness is today's waste, and the progress of technology is or ought to be one of decreasing waste.

1. VALUES

1.1. *Truth*

We all value adequate knowledge: adequate propositions (in particular data and hypotheses) and adequate proposals (in particular rules and plans). Our notion of adequacy embraces two concepts, those of truth and usefulness. An adequate proposition is said to be true (to a considerable extent), whereas an adequate proposal is said to be useful (to a considerable extent). Thus the proposition that crème caramel is nourishing, is true, whereas a recipe for baking a good crème caramel is useful. In this section we shall study truth, leaving usefulness for the next.

Let us begin by recalling briefly some of the ideas on truth discussed at length in Vol. 2, Ch. 8; after that we shall have a new look at the problem. To begin with we stipulate that truth (total or partial) is a property of propositions that have passed certain tests. This statement raises immediately two questions: Why should propositions, rather than sentences, be the truth bearers, and why should propositions lack a truth value unless they are first tested? The answer to the fist question is this. Firstly, not all sentences are meaningful, hence not all of them could be assigned a truth value. For example, 'This book squeezes my anvil', though grammatically correct, has no cognitive content and therefore does not designate a proposition. Second, the language in which a proposition is expressed is important only for purposes of communication. Thus the sentences 'Russell was a famous thinker' and 'Russel fut un penseur célèbre', as well as their renderings in American Sign Language, express the same (true) proposition.

As for our view that propositions are not born with truth values but are assigned truth values on the strength of tests, it is at variance with tradition. According to this tradition, which probably originated with Plato, truth (or falsity) is possessed by a proposition whether anyone knows it or not. This view is still found, though usually unexamined, in much of contemporary epistemology. In particular epistemic logicians usually equate "s knows p" with "s knows that p is true". Yet there are two different concepts here: subject s may know or understand p without having the slightest idea about the truth value of p. For example, a theorist who conjectures or infers a hypothesis p will not know whether p is factually true until p has been subjected to empirical tests—and even then some uncertainty may remain. In short, a proposition p must be distinguished from the metastatement "p is true (or false)", which in turn can only be a result of an investigation of p.

We adopt then the constructivist thesis that propositions, and in general constructs, exist (formally) if, and only if, they are knowable. In particular, truth values are acquired or lost as a result of tests for truth. This does not prevent us from *feigning*, for the purposes of logical or mathematical work, that there are constructs, in particular propositions, detached from the material world and, in particular, from thinking brains (cf. Bunge, 1981). We adopt this as a useful fiction and as tantamount to saying that, for certain purposes—such as logical analysis and mathematical calculation—it does not matter who thought up the propositions concerned or under what circumstances he did so. Pretending that propositions exist in this manner is radically different from claiming that they exist in and by themselves, the way Plato, Bolzano, Hegel, and Popper held. Our view is then compatible with the naturalist ontology formulated in Vols. 3 and 4.

Our constructivist thesis is superficially similar to that of operationism, according to which physical objects have no properties as long as these are not measured. The analogy is superficial, for physical objects happen to exist by themselves, and every existent has some properties. On the other hand constructs must be constructed by someone in order to exist. It is we who, by fashioning them—i.e. thinking them up—endow them with properties, in particular truth values—or abstain from doing so. Table 12.1 summarizes our view so far.

The kind of test that may determine the truth value of a proposition depends on the kind of proposition. Thus the (formal) truth of the Pythagorean theorem is established by deduction within Euclidean geometry, whereas its factual adequacy is investigated by measure-

TABLE 12.1
Truth not inborn but acquired or lost

Methodological viewpoint	*Semantical viewpoint*	*Pragmatic viewpoint*
p has not yet been investigated, or it has been studied and no conclusive results have been obtained.	*p* has no truth value.	Suspend judgment about the worth of *p*: neither believe nor disbelieve *p*.
p has been investigated and found coherent with both background knowledge and new data.	*p* is true (to some extent).	Accept *p pro tempore*.
p has been investigated and found inconsistent with background knowledge and new data.	*p* is false (to some extent).	Reject *p pro tempore*.

ment—which shows it to be approximately true of physical space. There are then, as Leibniz argued, truths (and falsities) *of reason*, and truths (and falsities) *of fact*. We count the logical, mathematical and semantical among the former, and the ordinary, scientific, technological, ontological and epistemological among the latter. A truth of reason is recognized by its coherence with some body of knowledge, i.e. by purely conceptual operations. On the other hand a truth of fact is recognized not only by its matching a body of (factual) knowledge but also by its passing certain empirical tests showing its adequacy to concrete or material reality. See Figure 12.1.

Because formal and factual truth are predicated of propositions of radically different kinds, and on the strength of operations of diverse types, each of them requires its own theory. That is, we need a *coherence* theory to elucidate the notion of formal truth, and a *correspondence* theory to explicate that of factual truth. The claim that a single theory of truth can perform both tasks is consistent only with either an idealist ontology or a radical empiricist epistemology. In the former case reality, or the actual world, is just one more model of some abstract structure. In the latter case all knowledge, whether formal or factual, is acquired only through sense experience: the task of reason would be only that of ordering or systematizing such knowledge, never generating or validating it. Since we accept neither an idealist ontology (cf. Vols. 3 and 4) nor an empiricist

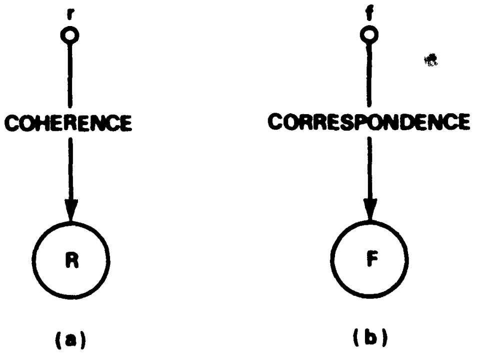

Fig. 12.1. Two kinds of truth. (*a*) Formal truth: proposition *r* coheres with body *R* of propositions. (*b*) Factual truth: proposition *f* corresponds to facts *F*. Since *R* and *F* are disjoint, the relations of coherence and correspondence are different.

epistemology (as is clear from this volume), we reject the monistic view of truth, which conflates formal and factual truth, and we undertake to find one theory for each kind of truth (or falsity).

Now, the coherence theory of truth is available: it is part of model theory, or the semantics of logic and mathematics, and it is usually included in logic. On the other hand the correspondence theory of truth is so far little more than a program. We shall not be concerned here with formal truth and its theory, i.e. model theory, of which more in Vol. 2, Ch. 8, and Vol. 6. We shall grapple instead with the idea of truth as correspondence with fact. Our investigation will proceed in two stages. In the first we shall study what the correspondence consists in; in the second we shall investigate the actual process of truth value assignments, or the problem of truth criteria.

Our first problem, then, is that of clarifying the sense of 'correspondence' or 'adequacy' in the scholastic formula *Veritas est adaequatio rei et intellectus* (or *intellectus ad rem* in a more realistic version). How can a proposition, which is a construct, be adequate to (or match or fit in with) a fact in the world of things? One answer is that there is an isomorphism between a proposition and the piece of reality it refers to: this idea has been upheld by naive realists and Gestalt psychologists. However, 'isomorphism' is here as little a technical term as 'adequacy' in the scholastic formula. Indeed, isomorphism can exist only between sets, and neither a proposition nor the concrete thing it refers to are sets. This difficulty is seemingly solved by postulating that sets of propositions, such as theories, can correspond to collections of facts. But then truth would be a collective or emergent property possessed by a theory, not by its constituents. Besides, sets of facts have rarely a definite structure. Systems do have definite structures, but not every thing is a system. Besides, it is easy to exhibit systems that are not isomorphic with their theories—e.g. a system composed of two particles gravitating around each other is not isomorphic to any theoretical model of it, which model contains infinitely many propositions.

We seem to be up against a Gordian knot, so let us cut it. Let us not pretend any longer that the truth relation holds between propositions and facts. Let us admit instead that propositions can match other propositions, and facts other facts. And let us assume that the correspondence we are seeking is one between mental facts of a certain kind and further facts, whether mental or not. Further, in line with psychobiology we identify mental facts with brain processes occurring in plastic neural systems (Ch. 1). This strategy will allow us to characterize (though not define in general terms) the concept of true partial knowledge of fact; once in possession of this notion we shall proceed to define the truth of a proposition.

Consider a thing a internal or external to an animal b endowed with a brain capable of learning. Call e an event (change) in thing a, and e^* the corresponding perceptual or conceptual representation of e in the brain of b. Then we say that b has gained *true partial knowledge of fact* e if, and only if, e^* is identical with the perception or conception of e as a change in thing a (rather than as a nonchange, or as a change in some other thing). The true partial knowledge that b has acquired of event e is the neural event e^*; and the *correspondence* involved in it is the relation between the events e and e^*.

Consider next the case where the object of knowledge is a binary relation between events, such as the temporal succession of two flashes of light. Let now e_1 and e_2 denote changes occurring in a thing a internal or external to an animal b capable of learning, and call e_1^* and e_2^* the perceptions or conceptions that b forms of e_1 and e_2 respectively. Further, let e_1 be R-related to e_2, i.e. Re_1e_2. We stipulate that b has *true partial knowledge of the fact that* Re_1e_2 if, and only if, (a) b recognizes e_1 and e_2 as changes in thing a (rather than either as nonchanges or as changes in something else), and (b) b perceives or conceives of e_1 and e_2 as being R-related, i.e. if $e_1{}^*$ and e_2^* are R-related. The true partial knowledge that b has gained of Re_1e_2 is $Re_1^*e_2^*$, and the correspondence involved is the relation between the event pairs $\langle e_1, e_2\rangle$ and $\langle e_1^*, e_2^*\rangle$. In general, the brain correlate of Re_1e_2 will be $R^*e_1^*e_2^*$, where R^* is similar to but not identical with R.

Consideration of the above two cases, of the single event and the pair of events, suffices for our present purposes. Let us now move from thoughts (brain processes) to propositions (constructs). Recall that we have defined a construct as an equivalence class of thoughts (Ch. 1, Section 2.1.) Consider the class of thoughts e^* elicited in animals of a given species by event e, and form the subset of e^*s that happen to constitute true (though partial) knowledge of e. Call this class $[e^*]$. No two members of $[e^*]$ may be identical—for they are thoughts of a given animal at different times or thoughts of different animals, and in either case they differ in some respect or other. However, they are all *equivalent* in that every one of them constitutes partial true knowledge of e; i.e. for every member e^* of $[e^*]$, e^* happens if, and only if, e is the case. We identify the proposition $p = \ulcorner e$ is the case$\urcorner$ with that equivalence class of thoughts, i.e. we set $p = [e^*]$. And we stipulate that *p is true if and only if e happens.* Likewise in the case of pairs of R-related events discussed above we form the equivalence class of thoughts $[\langle e_1^*, e_2^* \rangle]$ and identify it with the proposition $p = \ulcorner Re_1e_2 \urcorner$, stipulating that *$Re_1e_2$ is true just in case $R^*e_1^*e_2^*$ is the case.* In short, the correspondence relation that holds between a mental fact and some other (mental or nonmental) fact carries over to propositions in relation with facts. In other words, we have analyzed the fact-proposition correspondence into the relations shown in the following diagram:

$$\begin{tikzcd}
\textit{Facts } E \arrow[r] \arrow[dr] & \textit{Thoughts } E^* \arrow[d] \\
 & \textit{Equivalence class } E^*/\sim \textit{ of thoughts} \\
 & \textit{(proposition)}
\end{tikzcd}$$

In sum, we have identified factual truth with adequate knowledge of fact: we say that the proposition "e is the case" is true if, and only if, some animal has adequate knowledge of e. On this view truth and falsity are *primarily* properties of perceptions and conceptions, and only *secondarily* (vicariously) properties of those equivalence classes of thoughts we call 'propositions'. Hence a faithful perception or representation of a human figure can be said to be true, whereas a hallucination can be said to be a false perception. Moreover we identify the organ of truth and falsity as the plastic brain. It is a problem for neuropsychological research to try and localize, within the human brain, the neural systems that attribute truth and falsity.

Note that we have dealt only with simple (atomic) propositions, not with complex (molecular) ones such as disjunctions and generalizations. It might be thought that the latter can always be built out of simple ones, so that the truth values of the former can be evaluated on the basis of the truth values of the simple propositions together with a set of semantical truth conditions. This belief is false, as shown by any of the differential equations occurring in theoretical science. Thus a basic equation of Maxwell's electromagnetic theory reads: "For every electromagnetic field and the current that generates it, and every point in spacetime, the d'Alembertian of the vector potential of the field is proportional to the current density". This formula cannot be construed as an infinite conjunction of simple statements, one for each field and its corresponding source, and for each point of spacetime. Indeed the points of spacetime constitute a continuum, and logical conjunction is not defined for a nondenumerable set of propositions. The semantic truth conditions fail us here and we must resort to entirely different truth conditions, supplied by experimental physics and bearing on the testable consequences of the axiom in question.

Note also that we have dealt only with individual propositions not with hypothetico-deductive systems. One reason for this restriction is that an entire theory is unthinkable for it contains infinitely many propositions. We can think only of a few statements (postulates, definitions or theorems) of any given theory. When we think of a theory as a whole, in point of fact we select a handful of typical formulas of it. Therefore attributing truth or falsity to a theory is making an inductive leap on the basis of some evidence. (More in Section 2.2.)

It will be noted also that in the above discussion we spoke of *partial* knowledge of fact. Equivalently: factual propositions represent only some (not all) features of things, or they are not totally true but rather half true. Total truth and falsity, which are the only admissible ones in logic and pure mathematics, are hard to come by elsewhere. In applied mathematics, science, technology and the humanities, no less than in ordinary life, most statements are at best approximately true. In most cases we must settle for half truths in the hope of replacing some of them with three-quarter truths. Think of the rounding off of figures, the method of successive approximations, the errors of measurement, and the simplifications made in any mathematical model. Everywhere except in logic and in pure mathematics we deal with approximations and do our best to improve them. Therefore it behoves the philosopher to study error and its complement, partial truth. See Appendix 3.

Twelve centuries before Descartes' *Cogito, ergo sum*, Augustine wrote: "If I err, I am. For he that has no being cannot err, and therefore mine error proves my being. Which being so, how can I err in believing in my being?"

(*The City of God* Bk. XI, Ch. XXVI). Error is our constant companion, hence we should learn to live with it. We do so when learning from error and learning to correct it—which, by the way, is less frequent than learning from success. All observation, measurement or experiment is subject to error, and so is every nondeductive—in particular inductive and analogical—reasoning. However, without such operations we would hardly gain new knowledge. The rule therefore is not "Avoid error", good only for Superman. It is, rather, "Be not afraid of error but of refraining from exploring for fear of erring, and of being unwilling to correct error and learn from it". Moreover we should cultivate controlled error, or what passes for such, by questioning once in a while our most cherished beliefs and modes of thinking, to see whether they need alteration or, on the contrary, can be trusted for another while.

As there are two kinds of truth so there are two kinds of error: of reason and of fact. An *error of reason* is a mismatch among thoughts (or the corresponding propositions), whereas an *error of fact* is a mismatch between thoughts (or the corresponding propositions) and their factual referents. (However, both are brain processes and in this sense factual.) Each kind of error falls in turn into one of the following categories: of *omission* (overlooking propositions or facts) and of *commission* (misconception, misperception, or misdeed).

The most common errors, whether of omission or of commission, are of the following kinds:

(*a*) *erotetic*: asking the wrong question;
(*b*) *postulational*: assuming the wrong premises, be these presuppositions or explicit hypotheses or data;
(*c*) *dialectical*: advancing the wrong argument;
(*d*) *methodical*: choosing the wrong method or technique;
(*e*) *design*: designing the wrong operation, measurement, experiment, plan, or artifact;
(*f*) *computation*: making calculation mistakes;
(*g*) *sampling*: inferring from unrepresentative samples;
(*h*) *axiological*: wrong evaluation of, e.g. a proposition or a goal.

We say that an error is *wrong-headed* if it combines two or more errors of the above kind—e.g. the wrong problem with the wrong approach. (*Example*: Asking at what time the soul enters the human embryo, and looking for the answer in a theological treatise.) Characteristically, ordinary knowledge is plagued with errors of all the above kinds, often to the point of being wrong-headed. Worse, ordinary knowledge errors tend to be self-perpetuating (in popular myth) rather than self-correcting (as in science and technology). In particular, every time we announce a generalization from a hasty personal sample we commit a sampling error, often compounded by the contrary statement suggested by an equally nonrepresentative sample.

Design errors deserve a special comment. In measurement or experiment they are called *constant, systematic*, or simply *biases*. They are mistakes in the design of the operation, e.g. lack of adequate controls, or electrical leaks. Once detected they may be corrected, often completely. Such constant errors must not be confused with random errors, such as typing errors and the fluctuations around the average of a set of measured values. These other errors are really random: they have a regular statistical distribution (usually bell-shaped or gaussian). Although they can often be reduced, they can never be completely eliminated because they are rooted in objective randomness—e.g. the random thermal motions in both the measured object and the measuring instrument. (For this reason they should not be called *random errors* but perhaps *random scatters*.) Since chance is universal, random errors can be studied regardless of the nature of the measurement or experimental set-up. In fact they are studied by the mathematical theory of errors of observation, an application of the calculus of probability. On the other hand, since the constant (systematic) errors depend upon the nature of the components of the experimental set-up or its manipulation, there can be no general theory of constant (or design) errors.

Luckily we possess error detection mechanisms and have invented error correction procedures; moreover, both are perfectible with learning. The human brain seems to be equipped with error detecting and correcting systems—sensory, motor, and conceptual. The efficiency of such systems improves with (successful) practice and deteriorates in pathological conditions. For example, under the action of neurotropic drugs, or in the presence of brain disease or injury, such error detectors fail, and consequently the performance of mental activity becomes suboptimal; the electrical stimulation of such detectors affects them likewise (Bechtereva, 1978, pp. 134ff.)

Wiener (1948) conjectured that every error-correcting mechanism is cybernetic. To understand this recall that every error is a discrepancy or deviation, e.g. from the truth, or from some desired or normal value. Thus, in the case of a numerical variable, if the actual value is *a* and its correct (or optimal) value c, then the error in that variable is the absolute value of their difference, i.e. $\varepsilon = |a - c|$. If this discrepancy in the output of the system concerned overtakes a tolerable threshold, the control system is activated, and adjusts the input so that the error will decrease. This cycle is repeated until the (intolerable) error vanishes. We have become accustomed to thinking that such negative feedback mechanisms are common to inquiring systems and artificial control systems.

No doubt, errors in the performance of sensory-motor tasks and elementary intellectual operations are likely to be corrected (if detected) in this manner, i.e. by activating feedback loops in existing neural systems. However, the recognition and correction of bulkier errors, such as choosing the wrong problem, the wrong approach, or the wrong world view, may require far more than an existing feedback mechanism. Such errors may call for a radical reshuffling of neural connections—i.e. a self-reorganization—and the corresponding emergence of new conceptual systems.

When rendered conscious, the error correcting processes take the form of *methods* such as the dialectical method, the hypothetico-deductive method, the method of successive approximations, the statistical method, and the experimental method. One uses Socrates' (not Hegel's) *dialectical method* when investigating a set of premises, such as hypotheses and data. If they turn out to be utterly irrelevant or false, one discards them; but if they are relevant and one finds a grain of truth in them, one attempts to refine them, render them consistent with the antecedent knowledge, or adjust some of the latter to the new finding. (This procedure is not dialectical in Hegel's sense because it does not involve concepts that "contain their own negation"—whatever this may mean—and does not advance from contradiction to contradiction but from ignorance to knowledge, from falsity to approximate truth, from stray bits to systems, or from shallowness to depth.) The *hypothetico-deductive* method, or method of hypotheses, is a particular case of the dialectical method: it consists in advancing hypotheses, investigating their consequences, and adjusting or eliminating the former if such consequences turn out to be false.

The *method of successive approximations* is another particular version of the dialectical method. In mathematics it usually works as follows. One poses a certain problem and tries to solve it. If the problem cannot be solved exactly (or in closed form) one obtains a first approximation, which serves as the basis for constructing a second order approximation, and so forth, until a sufficient approximation, or even an exact solution, is reached. In factual science and technology the method of successive approximations works similarly but not quite, for in this case there are no algorithms for advancing securely from one hypothesis to the next: one proceeds in zigzag until hitting on an acceptable hypothesis—or on none. However, one does follow a prescribed sequence of steps such as: Initial data–hypothesis 1–data 2–hypothesis 2–. . . –hypothesis n, or some other alternate chain of conjecture and evidence.

The *statistical method* is a particular case of the method of successive approximations, in which the hypothesis, which concerns an unknown population, is suggested or checked by investigating a random sample of it, and rechecked by resampling. Finally, the *experimental method* is the same thing, except that experiment is explicitly involved. All five methods are error correcting (or rather minimizing) procedures. And the last three—the method of successive approximations, the statistical and the experimental method—presuppose that truth is usually partial rather than total.

Error is the complement of truth: the smaller the former the greater the latter. In symbols, $V(p) + \delta = 1$, where $V(p)$ is the truth value of proposition p, and δ the relative discrepancy or error of p relative to some other proposition taken as a base line. The latter may be a datum if we are checking a hypothesis, or a law statement if we are checking a datum. In writing the above formula we have assumed that truth values are real numbers comprised between 0 (utter falsity) and 1 (complete truth). That is, we have assumed that V is a function from a set P of propositions (those that can be assigned a truth value) to the unit interval [0, 1] in the real line. We have also assumed that the truth value of a proposition is relative to some other proposition, which is not questioned when evaluating the former although it may of course be questioned in a different context.

TABLE 12.2
Truth value of proposition p assuming base line q is true, i.e. $V(p) = 1 - \delta(p,q)$

Discrepancy $\delta(p,q)$	*Truth value* $V(p)$	*Vernacular*
0.0	1.0	p is true relative to q (rel. q)
$0.0 < \delta \leq 0.2$	$1.0 > V(p) \geq 0.8$	p is approximately true (rel. q)
$0.2 < \delta \leq 0.4$	$0.8 > V(p) \geq 0.6$	p is half true (rel. q)
$0.6 < \delta \leq 0.8$	$0.4 > V(p) \geq 0.2$	p is three quarters false (rel. q)
$0.8 < \delta \leq 1.0$	$0.2 > V(p) \geq 0.0$	p is nearly false (rel. q)
1.0	0.0	p is false (rel. q)

Therefore our initial formula should be generalized to read

$$V(p) = V(q) - \delta(p, q).$$

Table 12.2 exhibits a few typical cases.

The discrepancy $\delta(p,q)$ may be equated to the *reliability index*, a widely used measure of the theory-data discrepancy. This index is defined as follows. Let p and q be propositions of the form "The value of property M for thing a is r", or "$M(a) = r$" for short, where r is a real number. If both p and q refer to the same thing, and q is adopted as the base line, then the discrepancy is defined as

$$\delta(p,q) = \frac{|m - m'|}{|m'|},$$

where m and m' are the numerical values of the property M according to propositions p and q respectively, i.e. $p = \ulcorner M(a) = m \urcorner$, $q = \ulcorner M(a) = m' \urcorner$.

The above reliability index or discrepancy can be generalized to sets P and Q of propositions, such as a set of theoretical formulas and the corresponding set of empirical data, by summing over the corresponding values:

$$\delta(P, Q) = \frac{\sum |m - m'|}{\sum |m'|}.$$

In particular, this formula covers both the case of checking theoretical calculations against observations, and of checking observations against calculations. But it applies only to a smallish sample of all the propositions of a theory, namely those that are actually subjected to tests. Moreover, that sample is not a random one, so if the theory-data discrepancy is small (large) we cannot safely infer that the theory itself (together with the subsidiary assumptions and the data necessary to derive testable consequences) is true (false). Finally, the above formulas apply also to the confrontation of theoretical propositions with other theoretical propositions, and of empirical data with other empirical data, provided the confronted pairs of propositions share a sense and a reference. For more on the way (partial) truth values are assigned in science see Vol. 2, Ch. 8, Sections 2.2–2.4. For theories of partial truth see Appendix 3.

Two warnings are in order. One is that, in general, there is one discrepancy value for each value of the variable(s) under experimental control. Hence as the experimenter explores different parts of the theoretical curve the discrepancy may well vary, i.e. increase or decrease.

Moreover this variation is *lawless*, because there is no logical or physical necessity linking the experimental data to the theoretical predictions.

The second warning is that experimental accuracy depends not only upon the quality of the instrumental, e.g. the laboratory equipment, but also upon the mathematical form of the formulas being checked—which form is to some extent conventional. A simple example will suffice to make this point. Suppose the task is to check a theoretical formula of the form "$y = ax/(b + x)$". This task is complicated by the fact that a is the asymptotic value of y, i.e. $y(\infty)$: see Figure 12.2. To facilitate the task, one performs the simple trick of transforming the given formula into a linear equation by means of the variable changes $x = 1/u$ and $y = 1/v$, which ensues in "$v = (1/a) + (b/a)u$". Now a is the reciprocal of the ordinate value at the origin, usually an accessible number.

Inductive logicians have proposed a number of acceptance and rejection rules for propositions, that are independent of the concept of truth. Scientists appear to abide, albeit tacitly, by a different set of rules, namely

$R1$: Accept (*pro tempore*) all and only the (sufficiently) true propositions.

$R2$: Reject (*pro tempore*) all and only the negates of the (sufficiently) true propositions.

$R3$: Suspend assent or denial of all and only the propositions that you neither accept nor reject (*pro tempore*).

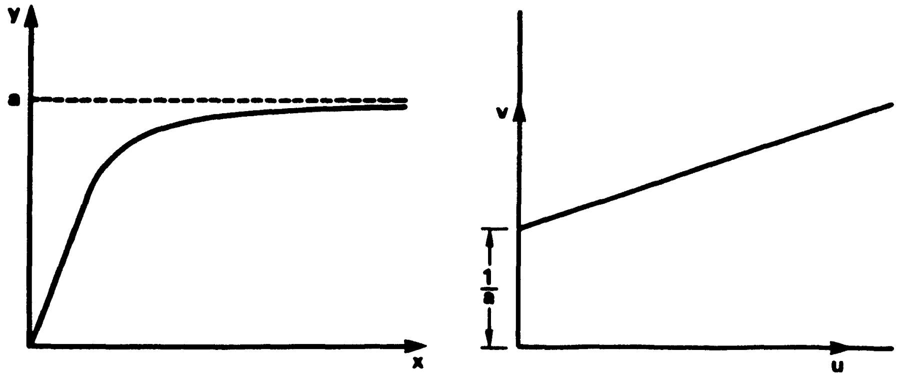
These rules can be unified and somewhat exactified by introducing three functions from the set of propositions to the set of decisions: A (acceptance), R (rejection), and S (suspension). The last two functions can be defined in terms of the first, namely thus:

$$\text{For any proposition } p,\ R(p) =_{df} A(\neg p),\ S(p) =_{df} \neg A(p) \,\&\, \neg A(\neg p).$$

The above rules reduce then to the single rule

R: *For all propositions* p, $A(p)$ *iff* $V(p) > l - b$, where b is the tolerance or maximal discrepancy allowable given the state of the art.

We close with a batch of assorted remarks. First, Wittgenstein (1953) and his followers have claimed that the concept of truth is dispensable: that every proposition of the form "p is true" can be replaced without loss with "p". This no-truth thesis about truth is logically and factually mistaken. It is a logical mistake because "p is true" is a metastatement, not a statement. (In other words, $p \neq \ulcorner V(p) = 1 \urcorner$.) The thesis (known as "the absolute theory of truth") is factually erroneous because scientists and technologists want to know whether their hypotheses are true, and this is why they check whether they "fit" the data. (The very notion of goodness of fit involves the concept of partial truth.)



(a) (b)

Fig. 12.2. Accuracy dependent upon mathematical form of hypothesis. A mere change of variables transforms the arduous task of determining the asymptotic value a into the far easier one of measuring the ordinate $1/a$ at the origin in (b).

A related doctrine is conventionalism and, in particular, fictionism, according to which the scientist does not seek truth because he investigates phenomena not reality. "He seeks system, simplicity, scope; and when satisfied on these scores he tailors truth to fit" (Goodman, 1978, p. 18). Let us gloss over the unfortunate fact that the author of this quote does not explicate the notions of simplicity and scope: suffice it to say only that, if scientists and technologists did not care for truth, and could make it up, they would not devote so much time to checking their information and testing their hypotheses for truth.

It is usually held that truth values do not really change in the course of time: what may happen is that sometimes we fail to discover their real truth values. This view presupposes that truth values are intrinsic or absolute rather than relative to some body of (empirical or theoretical) evidence. The obvious question is: How does anyone know that a given proposition has a certain truth value before it has been tested (or perhaps even formulated)? As long as no satisfactory tests have been performed we had better abstain from assigning truth values, i.e. from formulating metastatements of the form "$V(p) = v$". Factual truth values are assigned on the strength of tests and, since these are fallible, truth values are transient. This does not entail that truth, like fashion, is quite arbitrary: it does entail instead that truth, like fashion—and like everything else in matters of knowledge—is changeable.

Does the transience of truth values mean that factual knowledge is only probable in the technical sense, i.e. that truth is the same as probability? Clearly, truth differs from objective (physical) probability, or propensity.

Thus consider a thing that can be in any of n different states with equal probability $1/n$. The truth value of "The thing is in state m", where m is one of the n states, is either 0 or 1. This example suggests that there is no lawful relation between objective probability and factual truth.

What about subjective probability? Could we speak of the chance of a proposition being (totally) true, and equate that chance with the subjective probability of the proposition? This is what some philosophers have proposed. Since they take probabilities to measure intensities of beliefs, it turns out that the chance of a proposition being true equals the intensity of our belief in it. In other words, they propose the formula *p is true for subject s if, and only if, s believes strongly that p.* Thus truth would be just as subjective as belief. Consequently science and technology would have no more claim to truth than myth and religion. True, most proponents of subjective or personalist probability do not draw this consequence: they are inconsistent. But we insist on evaluating philosophical views by their fruits.

Other philosophers have proposed to substitute intersubjectivity for subjectivity, advancing the slogan *True is what the majority of researchers believe.* This, the consensus view, has been defended by Fleck (1935), Polanyi (1958), Kuhn (1962), Ziman (1968), and Rorty (1979). True, consensus is an indicator of truth; but it is not the same as truth: remember the fable of the Emperor's clothes. Factual truth is not just a matter of belief but of evidence. So, the above slogan would be adequate if in turn one could prove that in all cases the majority of researchers believe only the propositions supported by plenty of evidence. But this is a matter for social psychology. In epistemology we are interested in finding out whether or not there can be such thing as objective truth estimated on the strength of tests and quite independently of the strength of the beliefs of individuals or even entire communities. This is why we care for confirmation (Section 2.1).

1.2. *Usefulness*

An item of knowledge, such as a theory or a plan, can be valuable cognitively, practically, or both. Obviously we prefer our knowledge items to be valuable in at least one way. And it is also clear that this desideratum is not satisfied by every cognitive item. Thus counting the number of pebbles on a given beach is likely to be just as worthless as devising a technique for catching ghosts. In sum, not all things are worth knowing—just as not all actions are worth performing.

Cognitive and practical value are deceivingly transparent. Actually they are rather difficult to define and attribute. Let us start by examining the general notion of value, which will be studied in detail in Vol. 7. There is, first, the naive notion of *absolute* value, such as it occurs in the question 'What is the value of this datum (or that proposal)?' This notion is imprecise, for every time we assign a value to an object we do so in some respect or other: an item may be good for something but worthless or even disvaluable for something else.

The notion we want is that of *relative* value, or value in some respect, such as it occurs in the statement that cosmology is cognitively valuable though practically worthless. We are often in a position to make reasonable qualitative value judgements such as "The value of item x in respect R is great (or small or nil or negative)". And we can analyze such a global value statement in some such way as this: "The R-value of x for thing (e.g. person) a in circumstance b and in view of desideratum c is great (or small or nil or negative)" (Bunge, 1962b).

An object that is valuable may be so in itself or as a means for attaining some other object possessing a value in itself. We speak accordingly of *intrinsic* and of *instrumental* value as two varieties of relative value. (Intrinsic value must not be mistaken for absolute value: whatever is valuable is so in some respect or other—in particular as a means or as an end.) If we could quantitate value we would say that the total value of an object equals the sum of its intrinsic and instrumental values.

(It may be possible to quantitate value, i.e. to assign a definite number to the value of every object of some kind in some respect. I.e. one might try to postulate that, for a certain kind K of objects, in a certain respect R, there exists a function V_R from K into the double unit real interval $[-1, 1]$. Hence one could write, e.g. $V_R(x) > 0$ for "x is valuable in the respect R", $V_R(x) = 0$ for "x is worthless in the respect R", and $V_R(x) < 0$ for "x is disvaluable in the respect R". This possibility will be explored in Vol. 8.)

A realistic way of looking at valuation is to do so in terms of the *relative and comparative* notion of value, occurring e.g. in the question 'Which of the items x and y is the more valuable in the respect R?' Indeed it is often possible to rank objects of a given kind (e.g. hypotheses) in a certain respect (e.g. testability), much in the way we grade students with respect to originality and industry. We shall assume that, at least in principle, every homogeneous set K of cognitive items can be ordered in a given respect, such as truth or practical usefulness. (The homogeneity condition means that we compare hypotheses to hypotheses, proposals to proposals, and so on.) In other words we postulate that $\langle K, \geq_R \rangle$, where K is a homogeneous set of cognitive items, is a partially ordered set, so that, for any x and y in K, $x \geq_R y$ or $y \geq_R x$. (I.e., $\geq_R$ is assumed to be a simple ordering of K.)

We are now in a better position to clarify the notions of cognitive and practical value. We stipulate that an item of knowledge is *intrinsically valuable* if it is, or is likely to be, a (sufficiently) true proposition. In other words, intrinsic value is, in matters of knowledge, identical to truth and, like truth, it comes in degrees. Secondly, we stipulate that an object is *instrumentally valuable for inquiry*—or *instrumental for inquiry*—if it is an epistemic operation—such as questioning or measuring—or part of one, likely to yield an intrinsically valuable (i.e. sufficiently true) piece of knowledge. Thirdly, we stipulate that a knowledge item is *instrumentally valuable for action*—or *useful* for short—if it is, or is likely to be, a means for attaining a practical goal (whether or not goal itself is valuable in a given respect). Note the cautious clause "is likely to be" in all three definitions: it is a caution not to write off a piece of information, or an epistemic operation, just because it looks worthless at first blush. It may well be that, on a more careful investigation, or under new circumstances, it turns out to be valuable.

From the above definitions it follows that truth, though always (intrinsically) valuable, may not be instrumentally valuable, i.e. may lead nowhere and, in particular, it may not be practically valuable, i.e. useful. It also follows that, for an object to be practically valuable (useful), it need not be intrinsically valuable. In particular, untruths and even lies may be useful for certain purposes—particularly though not exclusively evil ones. Finally, the cautionary "is likely to be" reminds us that, even though we evaluate every cognitive item, we should not regard such valuations as certain and definitive. To proceed otherwise is to be short-sighted.

A couple of examples will help grasp the above notions. Unveiling the stratigraphy of a given site is intrinsically valuable, for it contributes to our knowledge of our planet. And it may also be instrumentally valuable, for both cognitive and practical purposes. Indeed, knowing the kinds of rock layers and their order is instrumental to dating whatever fossils or tools may be found in the site, and it is useful to identify minerals or search for them. In other words, geology is intrinsically valuable (as a science in itself), it is valuable to other fields of inquiry, and it is also useful to the economy. Our second example is epistemology: it is intrinsically valuable for contributing to our knowledge about knowledge. But epistemology is also instrumentally valuable for inquiry, if only for clarifying certain key methodological terms such as those of taxonomy and theory. Finally, epistemology can be useful in designing science and technology policies, e.g. by elucidating the very concepts of basic research, applied research, technology, and technical service (such as the practice of engineering or medicine), and by showing that, on the whole, it pays to support the former in order to make progress in the latter.

2. EMPIRICAL VALUE INDICATORS

2.1. *Confirmation*

Truth is not manifest but there are truth symptoms or indicators. One of them is empirical confirmation or corroboration. We shall deal here with the empirical confirmation of hypotheses and theories. To begin with, we stipulate that a hypothesis p is *empirically confirmed* (or *supported*) by a datum e if and only if (*a*) e is empirical evidence for or against p (Ch. 11, Section 1.2), and (*b*) e is roughly as true as p or some logical consequence of p.

The concept of empirical confirmation can be considerably exactified in case both the proposition and the datum in question are quantitative statements, such as

p: The theoretical or calculated value of property M of object x in state y equals t. Briefly, $M_\vartheta(x,y) = t$.

e: The measured value of property M of object x in state y equals u plus or minus the relative random error σ. I.e., $M_\varepsilon(x,y) = u \pm \sigma$.

In this case we stipulate that p and e are *empirically equivalent to within the error* σ if and only if the difference between the theoretical value t and the average u of the measured values is smaller than the relative random error, i.e.

$$p \sim_\sigma e =_{df} |t - u| \leq \sigma.$$

Obviously, p and e are empirically *inequivalent* with respect to the error σ if and only if they are not empirically equivalent to within σ.

It is tacitly agreed, in all factual sciences, that empirical equivalence amounts to empirical confirmation, and inequivalence to disconfirmation. Therefore we adopt the postulate that a hypothesis is *confirmed* (or *supported*) by all the data that are empirically equivalent to it, and *disconfirmed* (or *undermined*) by all those that are empirically inequivalent to it. It is also tacitly agreed that, the more numerous and varied the empirical evidence favoring a hypothesis, the more strongly it is confirmed.

A number of philosophers have attempted to quantitate the concept of degree of confirmation (or corroboration) of hypotheses in terms of their probabilities or, alternatively, improbabilities. In fact an entire industry has developed out of those proposals. But, since the assignment of probabilities to hypotheses is arbitrary, such measures are arbitrary and therefore useless at best, misleading at worst, and in all cases alien to the ideal of objectivity. In science and technology probabilities are assigned only to random *events*, never to propositions. What is true is that probabilities of random events are sometimes used to evaluate hypotheses holding that certain events are not random. In this case the probabilities of events, not of hypotheses, are compared. An explanation of this point may be in order.

Consider the process of self-assembly of a macromolecule, such as a gene, out of its precursors or components. If one models such components as point particles colliding at random, one is able to estimate the probability that the macromolecule got assembled by chance. Since the resulting number is extremely small, one concludes that the precursors did not assemble by chance. If one believes in miracles, one assigns the formation of the molecule to supernatural agencies; otherwise one explains it in terms of interatomic and intermolecular forces such as hydrogen bonds. This kind of reasoning is done all the time in psychology and other sciences, and it has been polished by mathematical statistics. The key words are 'null hypothesis' and 'significance level'. A quick reminder may be welcome.

Suppose we are to test a hypothesis of the form "B depends upon A" e.g. "A causes B". The thing to do is to compare the test results with the rival hypothesis according to which the occurrence of B is a chance event independent of A: this is the *null hypothesis*. *Example*: An animal can press either of five keys, every one of which has a different letter painted on it; the experimenter wishes to test the hypothesis that the animal discriminated among them and has a definite preference for one of them. The null hypothesis is of course that the animal presses the keys at random, so that the probability of each letter being pressed is 0.20: this is the so-called *chance level*. If the animal does press any one letter with a frequency significantly greater than 0.20, i.e. *above the chance level*, the null hypothesis has been refuted and, by the same token, its rival has been confirmed: i.e. the animal has in fact learned. The significance level (p) is a measure of the "significance" of the above-chance result and so of the rigor of the test. More precisely, p is the probability of observing a difference with respect to the chance level when actually there is none. The value of p is adopted before the experiment is run and is usually required to be 0.05. This means roughly that, if the null hypothesis (chance) is true, then the data will exhibit a difference (with respect to the chance level) only once in every 20 times.

One point to note here is that neither p nor any other probability involved in the above test is the probability of a hypothesis or the degree of confirmation of it. Another point is that the experimenter, far from trying to disprove his own hypothesis, *attempts to refute its rival*, i.e. the null hypothesis. In so doing he inverts Popper's injunction. But of course he takes precautions: by adopting a low significance level, such as $p = 0.005$, the experimenter makes sure that it is unlikely that he will adopt his own hypothesis when in fact the null hypothesis is true. So, the test he gives his pet conjecture is severe although he makes no attempt to refute it: he aims for a *rigorous confirmation.*

At first sight a reasonable measure of the degree of confirmation (or disconformation) of a hypothesis by a set of data would seem to the ratio between the difference and the sum of the number of confirmers and that of refuters of the hypothesis, i.e. $c = (C - R)/(C + R)$. The value of this function is 1 for $R = 0$, $\frac{1}{2}$ for $R = C/3$, 0 for $C = R$, $-\frac{1}{2}$ for $R = 3C$, and -1 for $C = 0$. However, since these values obtain regardless of the total number $C + R$ of tests, as well as of their variety and rigor, they are hardly significant. In conclusion, the above formula is useless. The alternative formulas proposed by inductive logicians fare even worse.

Scientists, usually eager to pin numbers on almost anything, are wary of quantitating the degree of confirmation of hypotheses. Thus nobody in his right mind would say, e.g. that the degree of confirmation of the Schrödinger equation is $\frac{3}{4}$. All we find in the scientific literature is a ranking of empirical evidence strength: *very strong* (or *compelling*), *strong* (or *definite*), *weak* (or *presumptive*), *very weak* (or *indecisive*), and *nil* evidence for or against a hypothesis. Thus the hypothesis that terrestrial life emerged about 3,000 million years ago is judged to be very strong; that mental functions are brain processes, strong; that the neutrino has a nonvanishing mass, weak; that intelligence is inheritable, very weak; that there are superluminal particles, nil; and that acquired characters are inherited, very strong negative.

The weight of a body of empirical evidence depends on the status of the

TABLE 12.3
Impact of new empirical evidence on evaluation of hypothesis

Cases	*Intrinsic value*	*Effect on scientific community*
e confirms established *h*	Minute	Nil
e undermines established *h*	Medium	Weak
e confirms new unrivalled *h*	Great	Strong
e undermines new unrivalled *h*	Small	Weak
e confirms new rival *h*	Great	Medium
e disconfirms new rival *h*	Medium	Weak
e inconclusive for or against established or new *h*	Nil	Nil

hypothesis it is relevant to: it is not the same for an established conjecture as for a new one. And the impact of new evidence on the scientific community depends not only on the intrinsic value of that evidence but also on a number of cultural factors. For example, the scientific community does not hail as enthusiastically as the mass media reports of the refutation of the theory of evolution, or of the confirmation of the hypothesis of telepathy. Table 12.3 exhibits the main situations with regard to both intrinsic value and social impact.

As can be seen from this table, the value of an empirical finding depends crucially on its relation to the hypothesis to which it is relevant. If the results are inconclusive one way or another, it is advisable to alter the experimental design so as to enlarge the sample, or render it more representative, or reduce the constant and random errors. The findings are of maximal value if they support a new unrivalled hypothesis or a new rival. They are far less weighty if they confirm or undermine an established hypothesis. In particular it takes more than a few unfavorable data to bring down a previously confirmed hypothesis. One does not rush to proclaim its demise but tries again, taking extra precautions or even altering radically the experimental design. This is particularly so if the hypothesis happens to belong to a theory enjoying empirical supports of several other kinds. In contrast, it takes only one conclusively negative finding to refute, at least for the time being, a new rival to an established hypothesis. (The latter may enjoy such an enormous prestige that any rival to it may be regarded as a crank not worthwhile testing—which is just as well in the majority of cases though unfortunate in a few.) And it takes many positive tests to conclude to the truth of a hypothesis.

How decisive can empirical findings be? In particular, are there crucial experiments? If by 'crucial' is meant a conclusive and therefore definitive verification of a given hypothesis or theory, then the answer is in the negative, for future alternative hypotheses or theories might account for the same, as well as further, empirical results at least as well. But if by 'crucial' is meant a finding allowing one to *reject* a given hypothesis or theory, or to *prefer* one of them to its known rivals, then there *are* crucial experiments (and measurements and observations). Since existence hypotheses are best proved by exhibiting examples, let us proceed to do so.

Uncounted observations and measurements have refuted conclusively the hypothesis that the Earth is flat; by the same token they have confirmed conclusively the hypothesis that it is (roughly) round—so much so that we call this a fact. Likewise uncounted observations have refuted conclusively the hypothesis that the biospecies are fixed; and, *eo ipso*, they have confirmed conclusively the hypothesis that biospecies have evolved—though the exact manner of evolution is still *sub judice*. The cases of the hereditary transmission of acquired characters, of demonic possession, of the biological inferiority of certain human groups, of the immutability of the human mind, and of the permanence of all social institutions, are parallel: they have all been refuted conclusively and, by the same token, their negations have been confirmed conclusively. (However, note that it is far easier to confirm a negative proposition than a positive one. Thus the conjecture that the reader of this page is exactly 30 years old is likely to be false though perhaps not widely off the mark. Most readers will be instances of the statement that any present readers are not exactly 30 years old.) In short, the radical skeptic is wrong: empirical evidence *can* be found to refute hypotheses in a conclusive manner and thus to confirm conclusively their negates. It is not true that all hypotheses are equally wobbly and stay so forever, so that nothing is ever settled. For better or worse we do not have to start from scratch every morning.

As with hypotheses so with hypothetico-deductive systems: there *are* observations (or measurements or experiments) capable of tipping the balance, in a decisive manner, between two rival theories. One case will suffice to prove this existence hypothesis. Hertz's experiments on electromagnetic waves destroyed once and for all the action at a distance theories of electromagnetism existing in his time and showed the enormous superiority of Maxwell's field theory over them. This is as close to a proof as one can get in factual matters: it proved that theory T_2 (Maxwell's) was *truer* than theory T_1 (e.g. the Gauss and Weber theory)—without however proving that T_2 was true. But it so happened that, no sooner was T_2 accepted as *the* true theory of the electromagnetic field, than Planck found a flaw in it (blackbody radiation) and Einstein another (photoelectric effect). This showed that T_2 was in need of basic corrections. These were provided by quantum electrodynamics (T_3), which is not only more accurate but also far richer than T_2, and consistent with quantum mechanics to boot. Still, T_3 is known to have certain flaws (the so-called divergences) that call for the construction of an even truer theory T_4 which is still due. In conclusion, although no experiment (or measurement or observation) can conclusively verify any theory, some experiments allow one to make *decisive choices* between given rival theories.

Why cannot theories (hypothetico-deductive systems) be confirmed in a conclusive manner: why must we settle for choosing the best confirmed member of a pair of theories? One reason is of course that, unlike a hypothesis, a theory is a system of infinitely many statements. (Recall Ch. 9, Section 1.2.) We could not possibly check every one of them but must select, for test purposes, a finite number of hypotheses in the theory. So, even if all of these statements were to pass the empirical tests, there would still remain infinitely many untested propositions in the theory. The second reason for the impossibility of confirming conclusively (i.e. verifying) a theory is that, for it to be checked, it must be enriched with data and indicator hypotheses (Ch. 11, Section 2.2) and, possibly, with subsidiary hypotheses as well. In other words, it is not just the bare theory but the theory together with all such additional propositions—some of which are data and others hypotheses—that is confronted with the new empirical evidence. Consequently we may blame any unfavorable outcome of the test on some of the additives to the theory, and may propose to revise some of these. And if the test is favorable to a particular theory-data-indicator hypotheses-subsidiary hypotheses combination, we must still try further such combinations with the same theory. Should all of them succeed we may hazard to diagnose the theory as (sufficiently) true. However, strictly speaking no theory can be assigned a truth value, for such assignment would require checking its infinitely many formulas.

Popper (1959) has held that confirmation is worthless because it is easy to come by, whereas refutation requires severe tests and can be decisive. A number of cases confirm this view, but there also arguments in favor of the thesis that confirmation and refutation are equally cheap or costly depending on the background knowledge used to design and interpret the tests as well as on the severity of the latter. Let us first offer three cases that seem to lend inductive support to Popper's anti-inductivist methodology.

First case: "My dog keeps the ghosts away by wagging his tail" seems to be confirmed by the nonexistence of ghosts in his vicinity. (Actually there has been no experimental test of the hypothesis, for the dog has not been prevented from wagging his tail, and there has been no independent check on the ghosts hypothesis.) *Second case*: "Of the two hypotheses, creationism and evolutionism, the former is by far the better confirmed, for whatever happens is in the last resort the will of God". (Likewise no controls have been set up. Moreover it would be considered blasphemous to try and control or even monitor in any way the divine thoughts and deeds.) *Third case*: "There is plenty of evidence for witchcraft, such as the hundreds of confessions signed by witches during the 16th and 17th centuries, not only under torture but also spontaneously, and all of which read very much alike—a likeness that cannot be mere coincidence". (Needless to say the Inquisition did not conduct any experiments on the presumed witches, nor were these examined by 20th century psychiatrists to find out whether they were psychotics.) This case is of great methodological interest because it shows the crucial role played by the "interpretation" of data in the light of our background knowledge. Indeed, it appears that the said confessions were cast in the language of the demonology concocted by Dominican priests on the basis of pagan myths and Christian theodicy, much as our contemporaries undergoing psychoanalytic treatment talk, feel and dream as dictated by their therapists. Thus "the mythology created its own evidence, and effective disproof became ever more difficult" (Trevor-Roper, 1969).

The above examples confirm, then, Popper's thesis that empirical confirmation is insufficient for it can be had too easily for any hypothesis. But they also show what is wrong with his thesis that confirmation is unnecessary and that only refutation, or unsuccessful attempts at refuting, count. In the first place, all three cases discussed above were examples of observation, not experiment: if the proper controls had been incorporated into the observations, the results would have been different or, rather, there would have been no favorable results. Second, all empirical operations are dependent upon our background knowledge: data do not come bare but wrapped in presuppositions. By altering some components of this wrapping—some of the hypotheses or data included in it—we may be able to change a confirmation into a refutation or conversely. Thus if we believe in witches we shall tend to accept reports on witchcraft, whereas if we disbelieve in witches we shall discard them out of hand—or shall inquire into the mental health or the level of education of our informant. The point is that unfavorable empirical evidence is just as vulnerable as positive one to the falsities in the background knowledge against which it is evaluated.

There are further arguments against refutationism. One is that it is far from easy to confirm a precise theoretical prediction, such as that the 3489 Å (ultraviolet) line in the spectrum of lithium results from a transition between two bound excited states of the negative lithium ion (Carlos Bunge, 1980). Checking this prediction requires constructing a device for producing negative ions in a certain state and using ultraviolet spectrometry techniques. A second argument is that it is psychologically and methodologically false to pretend that scientists value only attempts to shoot down their favorite hypotheses. To be sure, one will examine critically his theories but, once built and checked, it is only human to wish to see them reconfirmed. Moreover, when convinced of their truth one will tend to disregard criticism. Thus when the noted experimentalist W. Kaufman announced in 1906 that his experiments had refuted the special theory of relativity, Einstein and Planck did not budge. Ten years later it was discovered that the experimental results had been vitiated by a leak in the vacuum system (Holton, 1973). Luckily neither Einstein nor Planck were falsifiabilists. They were only fallibilists.

As for the methodological need for confirmation, it is just as clear: there is no other empirical indicator of factual truth. This is why physicists are still withholding judgment concerning the hypothesis of the existence of gravitational waves, black holes, and magnetic monopoles until someone detects them. No theoretical argument and no criticism can substitute for clear-cut—even if revisable—empirical confirmation.

The above reasons suffice to reject refutationism (deductivism) as well as confirmationism (inductivism). Section 3, on the nonempirical indicators of truth value, will yield further arguments against those two doctrines. The view we adopt instead can be summarized as follows. First, confirmation and refutation usually come in degrees such as nil, very weak, weak, strong, and very strong. Consequently factual truth itself comes in degrees. Second, because hypothetico-deductive systems contain infinitely many propositions, and some of them (namely the data, indicator hypotheses, and subsidiary assumptions) originate outside the systems, these can never be fully tested. However, if two rival theories are testable at all then we can, at least in principle, find out which of them is the best confirmed by a given set of data. Thus a choice among theories is possible. Third, imprecise hypotheses and theories withstand empirical tests far better than precise ones. In particular the negation of an exact hypothesis—such as "$a \neq b$"—is in general easy to confirm and therefore of little use except as a guide in the search for alternatives. Negation is cheaper than affirmation.

Our fourth principle is that failure to refute a hypothesis may not be of much value, particularly in the case of existential hypotheses such as those affirming that there are black holes, vector bosons, and extraterrestrial intelligent beings. Indeed failure to find the thing conjectured may be blamed on unsuitable equipment or search tactics. Fifth, although confirmation is insufficient, it is indispensable for assigning (temporarily) truth to some degree. Sixth, every scientist subjects his conjectures to critical examination and asks his peers for comments and criticism on them, but he also wishes to defend them from destructive criticism if he believes them to contain some grain of truth. In criticizing a theory we should be rather generous, in defending it rather parsimonious: the former because we do not want to nip possible advances in the bud, the latter because we do not want to condone error. Seventh, the value of confirmation and refutation depends critically upon the quality of the antecedent knowledge employed to produce and interpret the data concerned. Eighth, in actual scientific practice hypotheses and theories are evaluated not only in the light of data but also in that of nonempirical criteria, such as consistency. This last point will concern us in Section 3.

2.2. *Efficiency*

Cooking and medical recipes, technical rules and moral norms, as well as instructions and programs, are not propositions but *proposals*. And they are not true or false but efficient or inefficient. (On the other hand a proposition of the form "Rule r is efficient" may be true or false.) However, the adequacy of proposals is (or ought to be) assigned on the strength of tests. Not tests for truth, to be sure, but tests for efficiency. Thus we want to find out whether a given prescription for curing a certain illness is efficient, and whether a certain social program for eradicating a given social plague works.

In principle, any given proposal may be efficient to some degree, or inefficient, or even counterproductive. In some cases we may quantitate such efficiency, i.e. we may assign a proposal an efficiency value comprised between -1 (maximally counterproductive) and 1 (maximally efficient).

And the efficiency of a course of action ruled by the given proposal, in attaining its goal, can in turn be set equal to the product of the efficiency of the proposal by the value (or utility) of the goal itself.

Practice, which is not a test of truth, is the ultimate test of efficiency. Hence efficiency tests must be given independently of truth tests. This is not, of course, the view of pragmatism and dialectical materialism, for which only practice counts. But this view is wrong, as shown by the uncounted theories in basic science that are practically useless and therefore neither efficient nor inefficient, as well as by the uncounted myths that have been highly successful—e.g. in recruiting believers and activists—without being true.

In general, then, efficiency is not equivalent to truth, let alone identical with it, and the two predicates are not related in any regular way. There is, however, one important case where such relation does exist, namely when a proposal is based on scientific laws. For example, if we have ascertained that events of type *A* are always followed by events of type *B*, and estimate that we can control or produce events of type *A*, then we can set up the proposal "In order to get *B*, do *A*", or *B per A* for short. As a matter of fact the same law justifies also trying the dual proposal "In order to avoid *B*, prevent *A* from happening", or *non-B per non-A*. That is, one and the same set of laws may be used as a foundation for a pair of proposals, one for attaining a goal and the other for avoiding it. We call such proposals *nomologically grounded* (or *justified*). And we stipulate that technology fashions and recommends only nomologically grounded rules, norms, and proposals. (More in Bunge (1967b).)

Note that basing a proposal on a set of laws bears on efficiency, not morality: thus the proposal might be the efficient killing of innocent people. Hence showing that a proposal is based on a set of laws justifies it only partially. A full foundation of a proposal to use means *A* to bring about goal *B* must include a moral justification of both means and goal. Likewise if we propose to prevent *A* from happening in order to avoid *B*, we must justify morally our not doing *A* as well as avoiding *B*. More in a while.

The differences and relations between a law and the proposals based on it are summarized in the comparison between the truth table of the former and the efficiency table of the latter: See Table 11.3. In it we have assumed, for the sake of simplicity, that the law statement "If *A* then *B*" is completely true rather than only partially true. (This form fits both causal and probabilistic laws. In the latter case the consequent reads "*B* with probability *p*".) And we have assumed that the efficiency of the correspond-

TABLE 12.4
Truth table of law and efficiency tables of rules based on law.

A	*B*	*If A then B*	*B per A*	*non-B per non-A*
1	1	1	*f*	—
1	0	0	0	—
0	1	1	—	0
0	0	1	—	*f*

ing proposal can be gauged by a number *f*. We have not set *f* equal to unity because a law statement usually refers to an idealized (in particular simplified) model of things of some kind. Such ideal conditions can often be approximated in the laboratory. On the other hand real life, which is the domain of practical proposals, is messy. Hence the efficiency of a proposal may be less than maximal even if the underlying law statement is extremely accurate. This does not entail that practical proposals can dispense with law statements. On the contrary, they have to involve further law statements to account for the complexity of real life situations.

Note the following additional differences between proposals and their underlying law statements exhibited by Table 12.4. To begin with, whereas the law statement "If *A* then *B*" has a truth value for all four combinations of antecedent and consequent, the corresponding proposals have efficiency values only in half of the cases, namely when the means *A* is in fact applied. In this case, if the goal *B* is achieved to the extent *f*, we infer that the proposal works to precisely this extent. But if *A* is not implemented then we cannot infer anything with regard to the efficiency of the rule.

Finally, whereas law statements are value free, proposals are not, since they all concern goals that are more or less valuable. Moreover the means as well as the goals may be the subject of valuation, not only economic but also moral. Therefore mastering a law of the form *If A then B* does not warrant jumping without further ado to the rules ***B per A*** and ***non-B per non-A***. We must also evaluate both *A* and *B*, and we should declare explicitly what our preferences are. Our conduct should then be guided by the following maxim: Try ***B per A*** if, and only if, (*a*) "If *A* then *B*" is a law statement, (*b*) *A* is attainable or feasible, and (*c*) *B* is desirable and moreover outweighs *A* by far. The dual role, *non-B per non-A*, is subject to similar conditions. Condition (*a*) is epistemological, (*b*) is technical, and (*c*) is axiological (possibly moral).

The above maxim starts with the word 'try' because the conjectured efficiency of a rule should be checked rather than being taken for granted. As suggested before, a proposed rule may have to be altered (in particular complicated) to cope with reality. Or it may have to be replaced with an alternative rule, in particular one involving a different means to the same goal. And different rules are likely to have different efficiencies. The truth of a law statement suggests the efficiency of the associated proposals but does not guarantee it nor, in particular, does it guarantee maximal success. Nor does success warrant truth: it only poses the problem of explaining why the given proposal works. Thus the apparent success of acupuncture in decreasing pain poses the scientific problem of uncovering the neural mechanism whereby acupuncture raises the pain threshold.

In conclusion, there is no simple relation between truth the efficiency. Consequently the relations between theoretical knowledge and practical knowledge, science and technology, and knowing and doing, are involved. In particular, technology does not flow automatically from science—nor the other way round. (Obvious moral for science and technology policy: Cultivate both.) Another consequence of the complex relation between truth and success is the inadequacy of pragmatism as a philosophy of either science or technology for, by conflating truth and efficiency, pragmatism accounts for neither.

3. CONCEPTUAL VALUE INDICATORS

3.1. *External Consistency*

Empirical confirmation, though necessary, is not a sufficient indicator of factual truth, and this for the following reasons. Firstly, in principle any number of hypotheses and a large number of theories can cover the same data. I.e. two or more inequivalent hypotheses or theories may enjoy the same inductive support—as was the case in the 16th century, though not in the next, with the sun-centered and the earth-centered planetary astronomies. Secondly, the zeal in fitting the data may be overdone. Thus by increasing the number of uninterpreted (phenomenological) parameters one can improve indefinitely the fit to any given set of data, though at the price of losing understanding and predictive power: overfitting does not pay.

In short, data are insufficient grounds for choosing among competing hypotheses or theories. Nor is internal (logical) consistency sufficient in the case of theories. Though necessary, this condition too is insufficient, for one can spin consistent theories at odds with the facts. This being so, there are two possibilities: either nothing can help us choose between two consistent and equally well-confirmed theories, or something can. To find out which is the case we must examine the way scientists and technologists proceed—rather than, say, consult some philosophical authority. This section and the next will be devoted to such examination.

When an investigator sketches his research plan—in modern parlance when he 'writes his grant application'—he makes sure that, no matter how novel his ideas may be, they do not clash with the whole of antecedent knowledge. To put it positively, our researcher takes it for granted, or attempts to show, than even his most heterodox ideas and procedures are congenial with our background knowledge or, rather, with the bulk of it. For example, if he proposes to investigate the hypothesis that inoperant ("selfish" or "junk") genes are fossil ones, i.e. nonfunctional vestiges of long past evolutionary stages, he will not question current mathematics, physics, chemistry, or even the bulk of genetics, let alone evolutionary biology.

We may say that the scientific investigator strives to keep or attain *systemicity* and, in particular, *external consistency*, or the compatibility of his new views with the bulk of antecedent knowledge (Bunge, 1967b). He may well be a revolutionary in one department but he cannot hope to upset the whole of science at one stroke—unless he is a pseudoscientist. The same holds for technological research, design, and planning, which are increasingly being based on applied science. True, the technologist may occasionally defy and refute the odd scientific theory, as was the case with the first aircraft designers, who had to ignore the primitive aerodynamic theory then prevailing. But, unless he is a bogus technologist, he will not go against the grain of mathematics and science; moreover, he will avail himself of as much applied science as he can lie his hand on. (Not doing so can be ruinous, as Edison learnt when he ignored the experts who had told him that, according to theory, alternating current was more efficient than direct current for transmitting electric energy.) In short, the technologist too values external consistency, and does so increasingly.

Why external consistency? Why could we not question everything at the same time? My answer is as follows. First, we *need* not question the entire body of knowledge: we question items of antecedent knowledge only as we find fault with them. Second, what we do need is to extend and deepen the existing knowledge, i.e. to face new problems. (Sure enough, as we proceed we are bound to revise some of the very body of knowledge that we used as our starting point.) Third, we need a launching pad, however wobbly it may be, for no problem can be posed in a vacuum. Every problem has presuppositions—which, of course, may be questioned provided we take some other propositions for granted. (Recall Ch. 7, Section 4.1.) Fourth, by using—at least temporarily—some of the antecedent knowledge we are assured of a fair amount of heuristic guidance and indirect empirical support. For example, if a new hypothesis implies or is implied by another hypothesis that has already passed empirical tests, then any direct support for each of them is indirect support for the other: see Figure 12.3. Fifth, even if we wanted to revolutionize the entire body of antecedent knowledge we *could* not do it, not only because every problem has presuppositions, but also because the evaluation of new ideas cannot be done in a vacuum and must not be done arbitrarily. Thus we shall be justified in preferring one theory to another only if the former accounts better for data or hypotheses that are not questioned for purposes of evaluation. Every well-grounded preference judgment is of the form "*A* is preferable to *B* with regard to (or in view of, or to attain goal) *C*", where *C* is not questioned during the comparison although it may eventually become an object of criticism. For all five reasons, although science and technology are in permanent transformation they cannot suffer total revolutions. We shall return to this point in Ch. 13, Section 3.2.

Let us watch the principle of external consistency at work. *Example 1*: Wundt (1879) rejected spiritism not for the dearth of empirical data in its favor but because it contradicts the best established scientific laws. (He also noted that magicians and mediums are better equipped than scientists to disclose the tricks of their colleagues, partly because scientists are used to acting in good faith and do not suspect any trickeries.) Hebb (1952) used likewise what he called the "external criteria" of physics and physiology, which "say that ESP is not a fact despite the behavioral evidence that has been reported". *Example 2*: Every time a new theory is proposed in place of an established one, it is judged not only as to internal consistency and empirical support, but also as to its harmony with the bulk of antecedent knowledge. Moreover the new theory is required to yield, in some limit or other, roughly the same correct results as its rival. Physicists call this methodological rule the *correspondence principle*, and most of them refuse even to consider any theories violating this requirement. And for a good reason, namely that external consistency, and in particular "correspondence" with a reasonably good theory, is a weighty truth indicator.

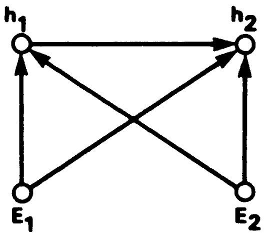


Fig. 12.3. If the hypotheses h_1 and h_2 are logically related, then every confirmer (or refuter) of one of them confirms (or refutes) indirectly the other.

Of course there is risk in applying the criterion of external consistency. By invoking it we may occasionally thwart a valuable piece of heterodoxy—but then error is the unavoidable hazard of inquiry. The principle serves not only to evaluate scientific hypotheses and technological proposals: it also spares us uncounted disasters by weeding out wrong-headed (ill founded) research projects and entire pseudosciences. To give it up would be to condone bogus science and deprive the serious investigator or inventor of any base line to start his inquiry, as well as of a guide to evaluate research plans and outcomes. It is no accident that Feyerabend (1975, Ch. 3) rejects the principle of external consistency and places magic, religion and pseudoscience on the same footing as science.

To prevent the principle of external consistency from enshrining dogma and stifling research it suffices to demand that (*a*) research produce new results—a standard requirement, and (*b*) our fundamental principles be subjected to critical scrutiny and systematization once in a while. The latter task is called *foundations research.* It is an established branch of mathematics but it still has to win acceptance in factual science, where observation and calculation are far more highly esteemed than discussion of basic principles.

The neglect of foundations research is mistaken, for unexamined principles may hide error or may need the company of further principles. And dismissing such research as "mere philosophy" betrays superficiality, for some fundamental principles of science and technology are in fact philosophical. For example, every fundamental physical hypothesis is required to comply with general philosophico-scientific principles such as those of antecedence ("Effects cannot precede their causes") and invariance with respect to observer changes as well as changes in the observer's standpoint or reference system. (For further philosophical principles of science and technology see the Introductions to this volume and to Vol. 3.)

Our view on external consistency as both a necessary requirement and a truth indicator is at variance with three popular philosophies of science: confirmationism (inductivism), refutationism (deductivism), and epistemological anarchism. The first exaggerates the value of examples (confirming instances), the second that of counter-examples (disconfirming instances), the third cares for neither ("Anything goes"), and all three views ignore the matter of external consistency. Yet even the most cursory examination of scientific practice shows that (*a*) data are not compelling by themselves (inductivism) or accepted by convention (deductivism) but only provided they cohere with some previously accepted data and theories; (*b*) a theory is not accepted just when it enjoys a strong inductive support (inductivism) or when all attempts at refuting it have failed (deductivism), but only when these two conditions have been met and, besides, the theory is consonant with some other theories (particularly theories about lower level entities); (*c*) the slogan "Anything goes" may be justified in matters of taste (though even here there are some restrictions) but not in matters of truth (science) or efficiency (technology).

In short, we postulate that every new proposition or proposal be compatible with the bulk (never the whole) of our antecedent knowledge. Moreover we submit that modern science and technology in fact abide by it. This postulate has the following consequences. First, failure to comply with it is a clear indication of pseudoknowledge—in particular bogus science or technology. Second, even though science and technology are characteristically changeable, there can be no total revolutions in them: every transformation, however deep, is local. Nearly total revolutions were possible before the emergence of modern science and technology: from then on every epistemic revolution has been and will be partial because it is a new growth in the midst of a vast system of knowledge. Third, because every body of background knowledge has philosophical (in particular ontological and epistemological) components: (*a*) the evaluation of every radically new proposition or proposal involves or presupposes philosophical considerations; (*b*) there are no frontiers between (good) philosophy on the one hand and the rest of knowledge (in particular scientific and technological) on the other; (*c*) the search for a demarcation criterion between philosophy on the one hand and science and technology on the other is futile (Bunge, 1973b); however, (*d*) since most of philosophy is still at variance with or at least remote from contemporary science and technology, only a deep and sweeping revolution in philosophy or an equally deep and sweeping counter-revolution in science and technology can bring about an overall consistency between philosophy on the one hand science and technology on the other.

3.2. *Other*

Internal and external consistency are not the sole nonempirical indicators of the value of propositions and proposals. Several others, some reliable and necessary, others less reliable and less desirable, or even ambivalent, have been proposed by a few scientists and philosophers. We shall list them with the help of an earlier study (Bunge, 1967b, Ch. 15, Section 15.7). Let us start with the reliable indicators, labeled '*R*'.

In the first place we have three *formal* or logical indicators of the value of scientific or technological hypotheses, theories, or proposals:

R1 Well-formedness: the propositions and proposals should be well-formed rather than gibberish. This condition excludes expressions such as 'The length of *b* is 3′, where the mention of a unit is missing, and 'That method is good', which fails to mention the goal.

R2 Systemicity: it is desirable that every construct be a system (classification or theory) or a component of it. This excludes strays, which are hardly intelligible and cannot be evaluated for truth or efficiency.

R3 Internal consistency: propositions and theories should be logically consistent. This excludes contradictions and demands that we reconstruct any theories containing them.

Next comes a *semantic* indicator:

R4 Interpretability: some mathematical formulas in a scientific or technological theory or proposal should be susceptible to interpretation in factual (though not necessarily empirical) terms. To this end we must join it to semantic assumptions determining what the various predicates refer to and represent. (For semantic assumptions see Ch. 9, Section. 2.2.)

In the third place we have a rather numerous collection of *epistemological* indicators, other than coverage and predictive power, which may be regarded as empirical:

R5 External consistency: i.e. compatibility with the bulk of antecedent knowledge: see Section 3.1.

R6 Consilience: "the evidence in favor of our induction [theory] is of a much higher and more forcible character when it enables us to explain and determine cases of a *kind different* from those which were contemplated in the formation of our hypothesis [...] No accident could give rise to such an extraordinary coincidence" (Whewell, 1847, Bk. XI, Ch. V, Section 11, p. 65).

R7 Unifying power: capacity of a theory to embrace previously separate theories—e.g. electromagnetic theory of light, neurophysiological theory of mind—or of a plan of action to bring together previously detached courses of action—e.g. a social program aiming at both job retraining and public works aimed at alleviating unemployment. Clearly, unifying power entails consilience.

R8 Depth: deep theories and techniques, involving fundamental mechanisms, are preferable to shallow ones. In science because deep theories give more than coverage, namely explanation; in technology because deep proposals expose the roots and allow us to control or alter them.

R9 Stability: the theory should not fail at the first unfavorable evidence, and the plan should not founder at the first practical obstacle, but both should be susceptible to repairs. However, stability has a limit. We do not want to save a theory by evasive manoeuvres such as adding further epicycles, for it may then become impregnable to disproof. Nor do we wish to save a plan by making so many compromises that it will not attain its goal.

R10 Heuristic power: new theories and techniques should suggest and guide research rather than just summarizing it, let alone blocking it.

R11 Originality: bold (yet not wild) theories and methods, enabling one to explore old territories in new ways, or to discover new ones, are preferable to well-tried and safe ideas. After all, the goal of research is to gain new knowledge or new power.

Now come two *pragmatic* indicators, particularly desirable in the case of applied science and technology:

R12 Methodological simplicity: the theory should not be so complicated that any calculations with its help, or any empirical tests of it, would be so time consuming that in practice it would remain fallow.

R13 Feasibility: techniques, designs and plans should be capable of being implemented by real people in real time rather than being suited to ideal people and situations.

Finally come three *philosophical* indicators:

R14 Compatibility with a science-oriented ontology: i.e. one of changing things rather than either unchanging entities or ghostly ones. This disqualifies the hypothesis of telekinesis and the proposal of solving the energy crisis by powering machines by psychic power.

R15 Compatibility with a science-oriented epistemology: i.e. one learning from science and thus capable of stimulating the search for true theories and proposals based on objective knowledge. This condition spares us the attempts to gain truths of fact by purely rational means, or by purely empirical ones.

R16 Compatibility with an ethics: enshrining human rights, in particular the right to know, and human duties, in particular the duty to teach and enlighten.

With two exceptions all of the above conditions are mandatory, hence they are good indicators of truth or usefulness. The exceptions are *R11* (originality) and *R12* (methodological simplicity), which are desirable but not absolutely. Moreover, occasionally they must be dropped altogether. For example, building a theory of the iron atom would not shake the foundations of physics but would still be a very distinguished achievement because of the many subsidiary hypotheses and the enormous computational difficulties involved. On the other hand building a theory of the precise way the nucleic acids synthesize proteins would constitute a revolution and it would probably be a theory difficult to apply as well as to test, just as general relativity was and still is.

A number of alternative nonempirical value indicators have been proposed from time to time, which I submit are unreliable and sometimes clear indicators of disvalue. Here are the most popular, each labeled '*U*'.

U1 Coherence: the articulation of a conjecture with other, previously accepted propositions, is the paramount criterion of truth. This is the thesis of the so-called coherence theory of truth (Blanshard, 1939; Rescher, 1973, 1979). This theory is correct in formal science, where it has been exactified and has become part and parcel of model theory (cf. Vol. 2, Ch. 8, Section 2.1). Moreover it has an important grain of truth with regard to factual statements for, after all, when weighing the truth of a proposition we do so by comparing it with other propositions. (In other words factual truth is always relative to some base line that, in turn, may be questioned as long as a further base line is adopted however provisionally. See Vol. 2, Ch. 8, Section 2.2.) However, internal coherence is insufficient, as shown by a number of consistent doctrines proposed by madmen and pseudoscientists. In the case of factual propositions we need also agreement with facts (correspondence) and external consistency, i.e. agreement with adjoining bodies of knowledge. In short, coherence is *a* truth indicator not *the* truth criterion.

U2 Simplicity: some kind of simplicity, logical, psychological, or practical, has been claimed to be the seal of truth. (*Examples*: the medieval slogan *Simplex sigillum veri*, Mach's *Denkoekonomie*, and the conventionalism of Philip Frank and Nelson Goodman.) To be sure we delight in simplifying, particularly in practical matters. But this is not always possible and it is usually undesirable in cognitive matters because the universe we wish to unveil happens to be complex. This is why the mainstream of scientific and technological progress has been a course of increasing complexity in all regards. Compare contemporary theoretical chemistry, based on quantum mechanics, with Lavoisier's. Besides, high speed computers can handle computational complexities that were formerly intractable: this has brought about a devaluation of simplicity. (For more see Bunge (1963).)

U3 Beauty: theories and methods should appeal to our sense of beauty. Yes, but what is beauty and why should it be related to truth or usefulness? A logically well organized (i.e. axiomatized) mathematical theory is likely to look beautiful to a mathematician or a philosopher, ugly to one interested only in applications, and revolting to a data collector. As with simplicity, beauty is welcome but uninvited.

U4 Longevity: the longer a theory or a technique has "survived" (i.e. been in use), the more adequate or better adapted it must be—so the misplaced evolutionary argument proposed by Peirce goes (see Rescher, 1977). True, some scientific theories (e.g. classical mechanics) and techniques (e.g. microscopy) have proved to be extraordinarily long-lived—but only because they have been refined and assigned more modest roles. If survival were a genuine truth or efficiency indicator, then we should accept as true or efficient all the ancient superstitions that are still with us. No, longevity is not necessarily a mark of truth or of usefulness: it can also be an indicator of ignorance. If anything, the older a cognitive item the sooner it is bound to be altered or even forgotten.

U5 Consensus: the goal of research is to win the consensus of the experts (Ziman, 1968. 1979). This is a double-edged idea. On the one hand it suggests complying with the criterion *R5* of external consistency, but on the other it collides with *R11* (originality) and therefore invites discarding heterodoxies, some of which are likely to carry the seeds of necessary revolutions. Fortunately consensus is not universal in basic science or technology, where controversy flourishes. Even the most widely accepted data, hypotheses, methods, designs and plans meet with criticism. (On the other hand applied science and textbooks are usually free from controversy.) Surely the dissenters are always in a minority: so are the innovators who are eventually proved right.

So much for the nonempirical indicators, both the reliable and the unreliable ones, of truth or usefulness. How are research projects and plans of action *actually* evaluated? What criteria does a supervisor, referee or client actually employ to encourage or discourage a given line of research or development? And how do scientists and technologists evaluate their own findings and those of their peers? There is no consensus on this matter. True, internal and external consistency, originality, testability, predictability (in particular serendipity, or the ability to forecast unexpected facts), feasibility, profitability, and a few other indicators are normally taken into account. In short, evaluation is done on the strength of a whole battery of tests, some empirical, others conceptual. (Only philosophers tend to believe that a single factor, such as simplicity, explanatory power, or predictability, is involved.) However, the entire battery is rarely if ever used explicitly: some indicators are not used, and none is assigned a definite rank, let alone weight. As Kuhn (1978, p. 331) says, they "function not as rules, which determine choice, but as values, which influence it".

Worse, in many instances extracognitive factors play a role in evaluation. Among such factors we may mention personal sympathy or animosity, school affinity or rivalry, excessive depth or originality (incomprehensible to the judge), and even ideological bias. All but the last are easy to understand though hard to forgive. The last factor, namely ideological bias, was highlighted by the Lysenko affair: as is well known the quack agronomist succeeded in beheading Soviet biology by accusing it of not complying with Marxism. Less well known is the case of classical economics, in particular Ricardo's: though at variance with many facts and lacking in predictive power, it dominated the British academic and business communities for an entire century because, among other reasons, it explained social injustice and discouraged social reform (Keynes, 1936, pp. 32ff.). Nowadays neoclassical economics, in particular monetarism, though equally at variance with reality and therefore powerless to predict anything, is upheld because it abhors state intervention and planning. In short, ideological factors do play a role in the evaluation of scientific and technological propositions and proposals. We shall return to this point in Ch. 14, Section 4.2.

The intervention of noncognitive criteria, as well as the intervention of false philosophies of science and technology, may explain the frequent failure of the peer review method. (The method consists in asking experts, whose names are not disclosed, to evaluate the projects and accomplishments of their peers in the same field.) The peer review method is double-edged. On the one hand it screens out much fraud and low grade stuff, particularly most of pseudoscience and pseudotechnology. But on the other hand it tends to perpetuate whatever views the referees happen to hold; in addition, anonymity gives them even the chance to exact revenge. That the method does not work to perfection has been shown by two experiments, which have shown that (*a*) the prestige of an author and his institution are decisive factors in the evaluation (Peters and Ceci, 1980), and (*b*) the fate of a particular grant application is half determined by apparently random elements (Cole *et al.*, 1981). Double-blind refereeing solves some of these problems but not all. In any case no better method of evaluation has been proposed, so we should try and improve on it. One way of achieving this goal is to educate scientists and technologists in the principles of the methodology and philosophy of science, so that they may abandon some of the grossest errors underlying valuational mistakes—such as that data are all that really matter, so that all measurements are worth doing, and no theories are worth considering unless they summarize data or help get more data.

4. CONCLUDING REMARKS

A proposition may be accepted (believed) only if, when subjected to suitable tests, it proves to be sufficiently true. And a proposal ought to be adopted (implemented) only if, on the basis of sufficiently true propositions, it promises to be useful to solve certain problems to a reasonable and good end. But truth and usefulness are seldom manifest: therefore we must resort to indicators.

There are many value indicators, some conceptual and others empirical. (The former may be assessed before any empirical tests are given: such preliminary screening spares much time and effort.) The value indicators may be grouped as follows:

Logical: well-formedness, systemicity, and internal consistency.

Semantical: interpretability in factual terms.

Epistemological: external consistency, coverage, accuracy, consilience, unifying power, serendipity, depth, stability, originality, and heuristic power.

Methodological: testability—i.e. confirmability and, when applicable, refutability as well.

Pragmatic: feasibility (in the case of techniques, plans and designs), methodological simplicity (i.e. simplicity of application), efficiency, and profitability.

Philosophical: compatibility with an ontology of changing things, a realistic epistemology, and an ethics of human rights, in particular the right to inquiry.

Such multiplicity of value indicators renders evaluation delicate but makes for responsible evaluations. In any case that multiplicity ruins the simplistic philosophies of science and technology, such as those summarized in the slogans "*A* theory is only as true as its predictions (regardless of its depth, accuracy, etc.)", and "*A* plan is only as good as its deliveries (regardless of the morality of both means and ends)". The actual process of evaluating propositions and proposals in science and technology is far more complicated than suggested by such simplistic philosophies, but it seldom takes advantage of the full battery of tests, to concentrate only on such properties as accuracy, originality, and usefulness. No wonder, for the scientists and technologists who evaluate the work of their peers have seldom given any thought to the principles of evaluation—principles that they may dismiss contemptuously as being "merely" philosophical.

Unfortunately philosophers retaliate by not doing much better when it comes to evaluating their own ideas. In fact the current standards of excellence in philosophy seem to boil down to smart argumentation (even if it involves ignorance of basic facts), triviality of the problem, possibility of compression into a simple slogan, and prestige of the philosopher's institution. I submit that there is a better way to evaluate a philosophical view, namely to subject it to the following three batches of tests:

Historical: Does the view have any sound historical roots, i.e. does it make contact with the best philosophical tradition? And is it original?

Logical: Does the view constitute a system, and if so is the system internally consistent?

Epistemological: Is the view compatible with the current mathematical, scientific and technological knowledge? Does it solve any interesting problems? Does it have any heuristic power?

When subjected to the above tests, the most popular philosophical views of the day turn out not to be systems, not to harmonize with science and technology, not to possess any heuristic power, and often not even to handle (let alone solve satisfactorily) any outstanding problems. This is a very sad state of affairs which calls for a revolution in philosophy. But the matter of revolutions in knowledge deserves another chapter.

PART V

VARIETY AND UNITY

CHAPTER 13

EPISTEMIC CHANGE

Knowledge, like food, can be stored—for a while. Some of it becomes stale and is eventually recognized as useless, or is no longer of interest to anyone. And whatever does stay is bound to become incorporated into more comprehensive and deeper bodies of knowledge. (Even the immortal Pythagorean theorem has become a particular case of a more general theorem in Riemannian geometry.) Therefore the investigator must be always on the run if he wishes to stay in the same place.

Knowledge is gained and lost in a number of ways: empirically and theoretically, gradually and through revolutions, by disclosing ever finer details and by joining entire fields of research. The more we know the more and harder problems are we able to pose and solve. And the less helpful the existing body of knowledge proves to be to solve new problems, the more it invites its enrichment or replacement.

Like everything new, new knowledge emerges from pre-existing items. And like any other novelty, new knowledge is elicited from within and in favorable external circumstances, and it must overcome resistance. The inner driving force of knowledge is curiosity and, particularly, disciplined curiosity. The external driving force is need and, in particular, the needs of industry, trade, and welfare. And the obstacles to research, hence to novelty in knowledge, are multiple: economic (dearth of resources), political (hostility or indifference to learning on the part of government officials), and cultural (inertia and ideology).

Given the historicity of knowledge, the epistemologist would be ill advised to ignore the history of science, technology, the humanities, and their respective bogus counterparts. And given the social conditioning of research, as well as its impact on modern society, he would be equally ill advised to ignore the sociology of knowledge. However, we cannot find out how knowledge evolves along society unless we know what knowledge is. Therefore epistemology cannot be replaced with the history and sociology of knowledge although it must learn from them.

1. COGNITIVE NOVELTY

1.1. *Cognitive Kinematics*

Recall a few landmarks in the history of human knowledge since the beginning of civilization a few millennia ago: the invention of writing and its use as a thinking tool as well as to record social and natural facts; formal education; the invention of time keeping and astronomy, of mathematics and logic; the substitution of history for myth; the secularization of at least part of the intellectual culture and the accompanying tolerance for some innovation and some dissent; the establishment of scientific and technological bodies, such as academies and observatories; the invention of scientific theory and controlled experiment; the emergence of hundreds of scientific and technological disciplines; and the practical applications of science, i.e. the conversion of arts and crafts into technologies. No doubt, we have come a long way in a period that is but a small fraction of the total time since the human species emerged.

However, by far the greatest number of mathematical, scientific and technological knowledge we possess today has been acquired since the beginning of the Modern Era, which began only five centuries ago. We are all familiar with the exponential growth of mathematical, scientific and technological knowledge over this period. Indeed specialized knowledge has been doubling in size every decade or so, so that its growth may be likened to that of capital at a compound interest of about 7 per cent per annum. The analogy is apt in so far as in both cases the total size at a given moment depends on both the rate of growth and the total size at an earlier time. This highlights the importance of background knowledge, i.e. of the general assumptions and the fund of knowledge. Moreover, we also have the cognitive analogs of bankruptcies and crashes, namely those caused by depressions, wars and invasions, by mistaken science and technology policies, and by irrationalist movements. The exponential growth of knowledge, like that of the world population, is a modern trend, not a law. (Knowledge grows only provided there are people willing and competent to work on new problems and to try new ideas and methods.) Like any other trend, the exponential growth of knowledge may be altered. In fact there are already signs of decline: see Section 4.2.

Mutability is an essential mark of mathematics, science and technology, just as stasis is one of ideology and pseudoscience. This holds for all branches of science and technology, even the classical ones. A look at the

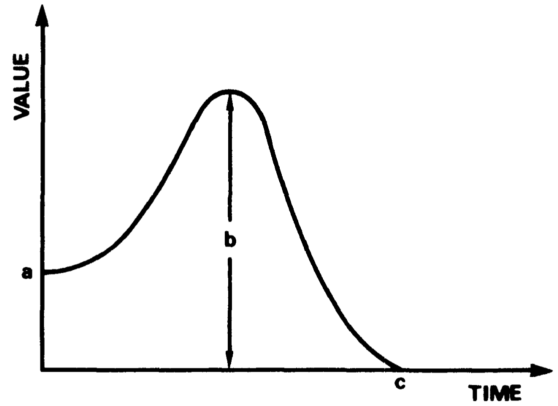

Fig. 13.1 Change in value of a cognitive innovation. Initial value = a; maximal value = b; life span = c.

scientific literature shows that new results keep cropping up even in classical mechanics and thermodynamics, as well as in plant morphology and genetics, in learning theory and human history. It is not only that new data and new hypotheses are found, or new applications are made: some of the very principles of such classical disciplines are modified once in a while. In the case of the classical physical, chemical and biological theories, such renewal is often associated with a modernization of the mathematical formalism. This change is so profound that Newton and Euler would be unable to read a contemporary advanced textbook in classical mechanics.

The value of data, hypotheses and techniques is time dependent. It may increase for a while after inception, reach a peak from which it may decline because the item has been superseded by more accurate information, more comprehensive or deeper theory, or more powerful method—or simply because it has ceased to attract interest. See Figure 13.1. Such decline in value is due to the very nature of inquiry, which consists in investigating problems with the aim of learning something new, i.e. of making original discoveries or inventions, some of which are bound to correct or even eliminate bits of knowledge gained earlier. Obsolescence, not perennity, is the mark of scientific findings and technological artifacts—just as discovery and invention is that of original scientific and technological research and development.

Originality, not only ability to learn much and fast, is the mark of the investigator, be it in science, technology, or the humanities. Originality, feared and repressed until a few centuries ago, is nowadays institutionalized, at least in mathematics, science, and technology. This institutionalization takes the forms of recognition of authorship or patent, and

TABLE 13.1
Phases of normal maturation of science

Phase	*Theoretical aspect*	*Empirical aspect*
0 *Prescience*	Unchecked speculation	Unchecked data
α *Protoscience*	Hypotheses formulated verbally, no theory	Observation and occasional measurement, no experiment
β *Deuteroscience*	Hypotheses formulated mathematically, no theory	Systematic measurement and experiment on perceptible traits of perceptible things
γ *Tritoscience*	Mathematical models (specific theories)	Systematic measurements and experiments on perceptible and imperceptible traits of perceptible and imperceptible things
δ *Tetartoscience*	Mathematical models and comprehensive theories	Precise and systematic measurements and experiments on perceptible and imperceptible traits of perceptible and imperceptible things

academic or pecuniary reward (cf. Merton, 1973). Only in the humanities are endless repetitions of ideas and scholastic commentaries on them, instead of the exploration of new ideas, still tolerated.

We may distinguish five main stages in the normal development of any field of factual inquiry: see Table 13.1. Note the qualifier 'normal': not all fields conform to our schema. For example, cosmology and economics, though mathematically very advanced and well stocked with precise (though insufficient) data, are still dominated by untested speculation; so, they exhibit some signs of maturity together with others of immaturity. (More in Vol. 6.) Also, some fields that teem with unbridled speculation and unchecked data, and so belong in phase zero, are sometimes advertised as scientific although they are clear examples of pseudoscience. (More in Ch. 14, Section 14.1.)

Different fields of research advance at different paces. Thus since mid century biology and history have made great strides, physics and sociology have advanced a fair stretch, psychology and economics only a little. Can the volume and speed of knowledge be quantitated and measured? Several measures have been proposed, such as the number of papers published and quoted. There is even an entire new discipline, scientometrics, with a journal of its own, that purports to gauge scientific and technological advance. However, counting papers and citations gives only an inkling of popularity, not of value.

There is no reliable measure, and no accurate measurement, of anything unless there is some underlying theory. So far we have not got a theory of the growth of science and technology. We only have a handful of rather vague principles, such as the following:

(i) The pace of inquiry in any given field is proportional to (*a*) the fund of knowledge accumulated in the same field, (*b*) the number of fields from which it draws background information, (*c*) the number of workers engaged in research, and (*d*) the number of problems it tackles.

(ii) Research in every field of inquiry can be likened to a river: (*a*) the *mainstream* formed by new lines of research and their continuation, (*b*) the *sidestream* constituted by routine investigations—or, to change the metaphor, it is made up of efforts to fill holes in a terrain the main features of which are already known, and (*c*) the *eddies* composed by barren controversies and heterodoxies (i.e. novel ideas clashing with the bulk of the fund of knowledge).

(iii) The power of any cognitive innovation (datum, hypothesis, method, or design) is proportional to the number of old cognitive items it displaces, and to the number of new cognitive items it renders possible.

(iv) The resistance to cognitive innovation is proportional to the degree of success of the extant body of knowledge which it seeks to displace, as well as to the originality and power of the new item. If there is no rival there is no resistance. If there is, the first reaction to the proposed innovation is to ignore it; the second, to try and find fault with it; the third, to attempt to assimilate it, i.e. to account for it in traditional terms; the fourth, to admit it; the fifth, to turn it into dogma. Resistance to innovation is maximal in stagnant fields. Thus economic theories are often accepted and repeated uncritically, and the economic "establishment" tolerates innovation "of the additive and amending type" but rejects radical novelty (Myrdal, 1973).

(v) Technical innovations are the most readily accepted, the better they satisfy deeply felt needs and wants, and provided they do not harm any powerful vested interests or call for the renunciation of whole life styles.

1.2. *Conceptual Change*

Understandably, philosophers are more interested in theoretical change than in any other type of change: they are interested in the emergence, development, and decline of theories, as well as in their replacement by rival theories. And they are interested in all the aspects of such changes—logical, semantical, epistemological, and pragmatic.

Theories are variously described as ideal objects, systems of changeable meaning and truth value, growing bodies of knowledge, or prescriptions for doing things. These characterizations, though very different, are mutually compatible. In fact from a logical point of view a theory is an ideal object of a certain kind, namely an infinite set of propositions closed under deduction. That one and the same theory may be variously interpreted, and may be attributed different truth values on the strength of different bodies of evidence, is obvious. From an epistemological point of view theories are not static but they grow in certain directions (as more theorems are proved and more applications discovered) and shrink in others (as regions of falsity appear). Finally, from a pragmatic viewpoint theories, even mathematical ones, can be used as rules or prescriptions for computing or for designing experiments, much as musical scores are used as instructions for performing. Since theories are all four—logical objects, semantic systems, growing bodies of knowledge, and prescriptions—according to the viewpoint that is chosen, there is no incompatibility among the four descriptions.

From a logical point of view theories are "already there in one piece" From this vantage point there is no difference between an axiom and the process of hypothesizing it, a theorem and the process of proving it, or a definition and the process of introducing it. Not so from a psychological or a historical point of view. Here definitions are not static identities but either inventions or discoveries of previously hidden identities. Here theorems are not just consequences of a set of premises: they are usually first guessed, then proved. And an axiom is not just an initial assumption that had always been "there" (in the theory): it is a hypothesis, usually tried long after a number of theorems are known. From a logical point of view every result obtained when working on a theory is a discovery not an invention: we only discover occult implication relations. From an epistemological viewpoint there is both discovery and invention: one makes new posits, introduces new concepts, and tries new strategies for constructing proofs.

From an epistemological point of view, a theory is not a self-existing ideal object but a potential body of knowledge that can be partially actualized by working on it. At any given moment we know only a finite subset of all the statements of a theory. This finite and variable collection of statements can be defined as follows. Call T a theory and s a knowing subject. The *part of the theory T known to s at time t* is the subset of the total set of formulas of T that s happens to know at t. And the part of the theory *known to mankind* at time t is of course the union of all such fragments for all the subjects familiar with T. In obvious symbols, $\Theta(s, t) = \{x \in T \mid s \text{ knows } x \text{ at time } t\}$, and $K(t) = \bigcup_{s \in \mathrm{H}} \Theta(s,t)$. Perhaps this, the known part of a theory, is what McMullin (1976) means by a 'dynamic theory'.

A second concept of philosophical interest is that of the family of specific theories built on a given general theory—or, to use the term introduced in Ch. 9, Section 1.2, the family of bound models of the theory. (*Examples*: every quantum-theoretical model of an atom or a molecule is a bound model; likewise every model of the evolution of a biospecies, or rather a biopopulation, is a bound model of the theory of evolution.) Call T a general theory and S_i a set of specific hypotheses and data consistent with T and couched in the language of T. Then the set of consequences of the union of T and S_i is the ith T-model, or $M_i(T)$. And the set of all T-models will be called the *T-family*, or $F(T) = \{M_i(T) | 1 \leq i \leq n\}$. Perhaps this is what Sneed (1979) has in mind when he states (wrongly) that a theory is composed by its hard core and the set of its applications.

Finally consider a historical sequence of theories T_k, each proposed at the corresponding time t_k over a period τ, and each dealing with a given domain (or reference class or universe of discourse) D_k. Moreover assume that the intersection $D = \cap D_k$ of these domains is nonempty. Then the *historical sequence of theories about D* over the period τ is $H = \langle T_k | t_k \in \tau \ \& \ k \in \mathbb{N} \ \& \cap D_k = D \neq \varnothing \rangle$. This seems to elucidate Lakatos's (1970) hazy notion of a research programme. But of course in factual science and technology theories are only part of the evolution of inquiry: there are also empirical investigations.

Broad and deep theories, such as classical mechanics and the theory of evolution, are likely to trigger a landslide of research based on them or inspired by them. Such theories are applied to uncounted new situations and they become paragons to be imitated—in short, they are regarded as paradigms or exemplars (Kuhn, 1962, 1970, 1974). Criticism, whether theoretical or empirical, is unlikely to stop the multiplication of models bound to such generic theories: victorious theories, like victorious politicians, are impatient with critics. Thus hardly anybody listens today to the correct charges of inconsistency made against quantum electrodynamics, or to the objection that "big bang" cosmology rests on flimsy empirical data. The paradigm becomes a paradogma. And, if criticism continues to be unheeded, the paradogma turns into dogma.

Eventually every theory is shown to be defective in some respect or other: in its mathematics, interpretation, accuracy, coverage, or all four. People formerly blinded by the successes of the theory start to admit that it is not perfect, and alterations are tried. Such changes range from minor adjustments to revolutions. In some cases the mathematical formalism is corrected or even thoroughly overhauled, as was recently the case with classical mechanics and classical electrodynamics (Truesdell and Toupin, 1960). In other cases the formalism is kept but the interpretation is altered, i.e. the semantic hypotheses are changed, as is the case with the objective reinterpretation of quantum mechanics (Bunge, 1967c). In still other cases the theory is replaced with another in the same style, as was the case with the change from classical to relativistic mechanics. Finally, in a few cases a whole new style of theorizing is proposed—as when Faraday and Maxwell invented field physics, Darwin and Wallace proposed their theory of evolution, and Lashley and Hebb revived physiological psychology. In such cases learning a new theory is not just adding knowledge but reorganizing from scratch what fund of knowledge one had and adopting a new mode of thinking.

From a semantical point of view theories can be compared as to meaning and truth. According to our semantics (Vol. 1 and 2) meaning is composed of sense and reference. The former is determined by the totality of logical relatives (implicants and implicates) of the construct of interest, whereas the reference of the latter is the class of (actual and potential) entities to which it applies (truly or not). The difference in sense or in reference between two constructs can be taken to equal their symmetric difference. Hence the total *difference in meaning* may be defined as the ordered pair: ⟨Difference in sense, Difference in reference⟩ (Vol. 2, Ch. 7, Section 3.3). In particular, differences in reference can be ascertained rather easily, particularly if the theory has been axiomatized. For example, field electrodynamics refers not only to the currents dealt with by action at a distance electrodynamics, but also to the fields accompanying such currents.

Another respect in which theories are comparable, and are actually compared, is truth. However, such comparison is far more difficult than that of meaning, for it cannot be performed a priori: in fact it involves the calculation of numerous examples and the corresponding empirical tests. Either operation is likely to be more difficult in the case of a rich theory than in that of a poor one: the number of variables and constants is likely to be greater, their interrelations more complex, and they are bound to be less readily accessible to measurement. Thus for several decades Einstein's theory of gravitation was judged superior to Newton's on the strength of only three "effects" in excess of those predictable by the latter. It took several decades of patient calculation of new solutions of Einstein's field equations, as well as ingenious new observations and experiments, to confirm that first impression. Still, the Newton–Poisson theory is so much simpler to apply, and it is such a good approximation, that it is used in the vast majority of astronomical and geophysical calculations. (This fact may come as a shock to the philosophers who believe that Einstein's theory "overthrew" its predecessor.)

In conclusion, rival theories are compared as to meaning and truth; they are also compared as to computational simplicity. Such comparisons are used as a basis for a rational decision among them. Hence it is mistaken to assert that rival theories built in entirely different styles (or involving "Gestalt switches") are mutually "incommensurable", so that the choice among them cannot be a completely rational act (Kuhn, 1962; Feyerabend, 1975). After all, two theories could not possibly compete with one another unless they yielded different answers to equivalent problems—such as alternative explanations of the existing variety of biospecies. And in order to share some problems the two rival theories must share some concepts and, in particular, they must have some common referents.

2. CHANGE MECHANISMS

2.1. *Usual Mechanisms*

Russell asked at one point: How comes it that we are able to know so much even though our individual experience is so limited? Chomsky (1975, p. 7) replied in a Platonic vein: "we can know so much because in a sense we already knew it, though the data of sense were necessary to evoke and elicit this knowledge". That is, experience would be nothing but the Socratic midwife that helps the innate knowledge come to light. There is of course no empirical evidence for this hypothesis. And there is plenty of negative evidence from the neurophysiology and psychology of development: it all points to the thesis that we are born ignorant.

The correct answer is that we are able to know so much because in principle there is no limit to what we can learn by sensing, thinking, and doing. And we can learn so much because our brains are plastic and because we inherit a tradition and learn from our contemporaries. As Bernard of Chartres said, we can see farther than the ancients because we are like dwarfs mounted on the shoulders of giants. That is, we do not have to start our inquiries from scratch because we can make use of the knowledge acquired by millions of people over thousands of years—and because we need not learn it all before tackling new problems. We are born ignorant though with the ability and drive to learn, and we are not born into a social vacuum but into a society that keeps some learning tradition or other. If this tradition happens to be one of inquiry rather than one of reverence for myth, we may learn as much as our genetic endowment and social status will permit.

Next to the innate knowledge thesis comes the combinatory view, according to which every new idea is the result of combining old ideas. There is plenty of evidence for this doctrine, which explains why the more we know the more we can find out. Indeed the more items are available for combination the greater the number and variety of combinations. (Thus if the number of items doubles from 5 to 10, the total number of binary combinations rises from 10 to 45; and if the former increases from 10 to 20, the possible binary compounds rise from 45 to 190.) But of course the combinatory view does not explain the origin of the first ideas or the emergence of radically new ideas. How did the Greeks hit on the idea of a proof: what elements did they combine in order to form it? How did Marx come to believe that human history is nothing but the history of class wars: did he merely mix up some ideas of Hegel's and Feuerbach's? The combinatory view holds only a grain of truth. In particular it applies to the original combination of ready-made parts to build a machine, and to the merger of theories—although it does not explain why some people conceive of such combinations whereas most don't. But combinatorics fails to account for the emergence of radically new ideas, such as those of atom, chemical reaction, gene, and social structure, which do not originate in the senses.

How then is the growth of knowledge, when it happens, to be explained? There are four traditional and influential views on the sources or movers of scientific, technological, and humanistic innovation: empiricism, rationalism, psychologism, and sociologism. According to *empiricism*, knowledge grows spontaneously as experience accumulates either by observation or by chance discovery. Theories would come, if at all, at the end of empirical inquiry and only as data summaries or at most to suggest further observations. Since empiricism regards data as irrefutable and as equally valuable, it imagines the growth of knowledge to be cumulative: it would proceed by the steady accumulation of data. No doubt, the production of empirical data is a necessary component of all factual inquiry; but the invention of theories and methods is another. Nor is it reasonable to doubt that there is some accumulation of data; but many data are in need of revision whereas others, even if accurate, cease to be of interest. In short, empiricism gives a one-sided description of the growth of knowledge: it fits at most the empirical side of protoscience and prototechnology.

On the other hand *rationalism* describes the theoretical side of the most advanced stages of science and technology. According to it, knowledge is self-constructed: it grows by inventing and criticizing ideas. Data would be only occasions for, and checks on, theorizing. The main movers of the inquiry process would be internal: the impulses to question, generalize, systematize, and explain. The growth of knowledge would be a sequence of ever better theories. Once in a while a bold new theory appears that kills its old rival. Knowledge advances thus by fits spaced by uninteresting routine activities. No doubt, this view holds an important grain of truth, but it fails to account for the entire process of research. For one thing fact finding is just as important as theorizing and it engages the vast majority of researchers. For another, new methods, particularly if allied to new and powerful instruments, can be just as revolutionary as new theories: think of the galvanometer, the mass spectrograph, the electron microscope, and the microelectrode. Thirdly, not all of the new and better theories kill their older rivals; thus relativistic quantum mechanics has not displaced the nonrelativistic approximation. In sum, rationalism has nothing to say about laboratory and field research, and gives a distorted view of theoretical progress.

Whereas empiricism and rationalism are popular among philosophers, psychologism and sociologism are often embraced by historians of knowledge. According to *psychologism*, knowledge is always the result of inquiry sparked off by either curiosity or need. Consequently the growth of knowledge must be explained exclusively in terms of mental or biological mechanisms. It would be foolish to deny that psychologism does tell part of the story. But obviously it does not explain why inquiry proceeds swiftly in certain periods and morosely in others, or why it flourishes in certain societies and is repressed in others. *Sociologism* makes up for these shortcomings of psychologism. In its moderate version it reminds us that every inquiry proceeds within a social matrix, so that, far from being a purely individual affair, it engages whole communities of inquirers. In its extreme version sociologism states that every bit of knowledge is a reflection of, or a response to, social conditions: that science, technology and the humanities are the products and mirrors of society. We have no quarrel with moderate sociologism even though it focuses on only one of the aspects of the inquiry process. On the other hand we find extreme sociologism unacceptable: after all, it is individuals, not communities, that perceive, think and act. There is no such thing as a collective brain or mind, just as there is no such thing as a Robinson Crusoe scholar. And a thousand mediocre researchers cannot do the work of a single genius—just as the genius would have nowhere to start from were it not for the dedication of uncounted modest researchers.

The most cursory look at the history of any research line in science or technology shows that each of the four views holds a grain of truth but is otherwise either incomplete or somewhat mistaken. There is no unique prime mover of inquiry: in some cases progress is made by performing new observations, measurements, or experiments; at other times by inventing new methods or new designs; at still other times by inventing new concepts, hypotheses or theories; occasionally also by criticizing or reorganizing known ideas; and always by contrasting ideas with facts, plans and artifacts with values, and so on.

Since each of the above partial views on the growth of knowledge is adequate in some respect, they should be consolidated into a fifth view free from the errors or exaggerations of the other four. This view acknowledges the roles of both experience and reason, as well as of the individual brain and its social matrix. This view results from the *biopsychosociological* approach to inquiry favored in the present book, and it suggests an integrated vision of the history of knowledge. Thus an adequate account of Harvey's work on the cardiovascular system must include such items as Harvey's medical experience and his familiarity with Galen and Vesalius; his acquaintance with the incipient mechanical world view, as well as with some mechanical contraptions, in the first place the pump; his ambition to understand the *humani corporis fabrica* described by Vesalius; his inquisitiveness and audacity (which cost him the loss of many patients); and his living in an age of discovery and invention in a society that tolerated both and was on the way to rewarding them. In other cases the intervention of formal organizations, such as universities, academies, churches, and political parties, must not be forgotten.

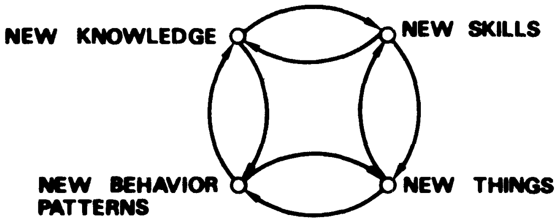

Fig. 13.2. Connections between epistemic and social innovations.

New knowledge sometimes causes social change, and at other times social innovation makes the acquisition of further knowledge possible. Moreover both epistemic and social innovation may result in increasing plant production, which ensues in greater food supply, which makes increase in population possible (not necessary), which causes the growth of cities, which stimulates the enrichment of culture (in particular the invention of new crafts), which favors the evolution of manufacture, trade and services, which in turn offer new opportunities for agricultural development. Likewise, from the 17th century on scientific innovations have sometimes triggered technical changes—such as electrical engineering and industrial chemistry—which have in turn revolutionized production, which has caused cultural and political changes, which in turn have stimulated advances in knowledge. See Figure 13.2. (For the chain-like character of technical and social innovation see Bourke (1978).)

Are such chains necessary? In particular, are discoveries and inventions inevitable? And as a consequence do science and technology have a momentum of their own, i.e. are they unstoppable? All we can say is that every epistemic accomplishment makes further gains in knowledge *possible*. Thus quantum mechanics made it possible to build modern solid state physics, which in turn made it possible—together with electronics—to design high speed computers, which in turn have revolutionized communications, industry and commerce. Without favorable social conditions none of these developments would have happened. They were epistemically possible and socially desirable: this is all we can say.

Yet, it is often stated that simultaneous discoveries and inventions by independent individuals *prove* that they are *necessary*: they seem to be "in the air" and emerge "when the time is ripe". They look as necessary outcomes of earlier work with no need for either genius or chance, or even promise of social reward. So much so that Merton (1973, Ch. 17) holds that what needs explaining is not independent multiple discoveries, for they are the rule, but singletons, which on closer examination should prove to be multiples, as is the case with the rediscoveries of unpublished or poorly circulated work. Merton exhibits an impressive array of data in support of his hypothesis, but does not discuss counterexamples such as Archimedes' statics, Netwon's dynamics, the electrodynamics of Faraday and Maxwell, or Einstein's general relativity. The latter deserves a special comment.

According to his coworker Leopold Infeld, Einstein believed that the special theory of relativity could have been invented by someone else, for a number of people—among them no less than Lorentz and Poincaré—were on the right trail. Not so the general theory. We should believe him, because nobody was interested in gravitation theory at the time: it seemed to pose no problems. Gravitation theory became a hot spot only thanks to Einstein. Even now the observational and experimental "effects" that only Einstein's theory explains and predicts are very small for the most part. Had it not been for Einstein's theory they might have passed unnoticed or, if noticed, they might have been explained in terms of perturbations, experimental errors, or some other *ad hoc* hypotheses.

We should not underrate the roles of genius and of chance. True, an isolated and misunderstood genius will work in vain; still, no scientific community will make great strides unless it contains some exceptionally talented and nonconformist leaders. True, discovery and invention do not spring out of nothing but require some background knowledge; but the researcher may come across some of it by chance—e.g. browsing in the library or meeting a stranger on a plane. In short, new knowledge comes about in ways that are biologically and logically necessary but socially accidental. (See Taton (1955) for the role of chance in scientific discovery.)

What holds for scientific innovation holds also for technical innovation: here too necessity combines with chance, and individual talent and pluck with social opportunity. The importance of the latter is clear from the fact that no industrial or social innovation is the automatic outcome of invention. For invention to fructify in innovation it must be practical and must be understood as useful by those who have the economic or political means to have the blueprints translated into artifacts or social programs. This is why only very few inventions are ever put to use.

To conclude this section: there are as many mechanisms of epistemic change as there are types of epistemic operation. Some workers go out into the field whereas others stay at the laboratory; some make observations and others experiment; some classify and others calculate; some draw blueprints whereas others build theories; some solve problems with the help of existing theories, and others criticize the latter; some delight in specificity, others in pattern; some split and others lump—and so on. The growth of knowledge requires that all of these and more epistemic operations be carried out concurrently in the scientific and technological communities. Breakthroughs may result from any of them. But none will occur unless society tolerates the free search for truth. We shall come back to this theme in Section 4.2.

2.2. *Reduction and Synthesis*

The rise of modern science was accompanied by the substitution of a mechanistic world view for the prevalent organicist one. The new model was the clockwork, not the organism; the new paragon was mechanics, not biology; the new judge was experiment, not dogma. The program of reducing every process to motion triumphed almost everywhere, though not without some philosophical opposition such as Leibniz's. It was not until 1850 that mechanism showed signs of exhaustion, particularly with regard to field physics, evolutionary biology, and social science. Mechanism is now dead. Nowadays only the odd philosopher believes that the world is made up only of particles. We know that there is no particle without field, that there are fields with no associated particles, and that in addition to physical objects there are chemosystems, biosystems, and sociosystems possessing emergent properties. (See D'Abro (1939) for the decline of mechanism in modern physics, and Vol. 4 for the supraphysical levels.)

Mechanism is dead but *physicalism*, or the program of trying to reduce every high level theory to physics, or perhaps to physics and chemistry, is still very much alive. Physicalism is both an ontology and an epistemology. The ontology of physicalism boils down to the thesis that concrete things differ only in complexity; its epistemology, to the thesis that every property of any whole can be understood in terms of the properties of its components. Such reduction would indicate the direction that the advancement of knowledge must take: "the number of principles needed to explain the totality of phenomena becomes ever smaller (...) Consequently, the number of explanatory principles used may serve as a measure of the level of knowledge attained, the highest being that which gets along with the fewest explanatory principles that are not themselves susceptible of further explanation. Thus the ultimate task of knowing is to make this minimum as small as possible" (Schlick, 1925, p. 13). On this view the progress of knowledge would consist in a progressive reduction of the number of ideas accompanied by a ceaseless multiplication of data.

According to the proponents of the reductionist program, only reduction can attain the unity of science, doubtless a desideratum. Thus the social sciences would be reduced to biology, which would reduce to physics: "each science is a special case of the one that precedes it (...) Biology is not 'just' physics and chemistry, but a very limited, very special and profoundly interesting part of them. So with ecology and sociology" (Medawar, 1974, p. 62). "In its simplest form the *unification program* consists in the unification of all branches of science by means of successive microreductions of the dynamic theories of these branches to one unified theory" (Causey, 1977, pp. 4–5).

How has the reductionist unification program fared? The history of science, technology and the humanities over the past century exhibits not only reductions but also mergers, not only unification but also diversification. The number of theories has become ever greater, and the number of branches of knowledge—even within physics and chemistry—has not ceased to grow. But at the same time the connections among theories and entire fields of research has increased. In short, we are heading towards the unity of knowledge through both reduction and synthesis, and in any case through enrichment not simplification, through interaction, not isolation. Thus we hope soon to be able to understand language not by reducing linguistics to physics or by keeping it detached from all the other branches of learning, but by integrating it with neuroscience, psychology, and social science. (More in Vol. 6.)

Why has the program of unification through reduction met with only limited success, so that we must look for a complementary mechanism—namely integration—to achieve the unity of knowledge? One reason is, no doubt, that the world is far more varied than imagined by physicalism: far from being flat it has a complex level structure: See Figure 13.3. A second reason is that a science is not a theory but a system composed of theories, methods and data, so that, even if the successive microreductions of theories were possible, this would not lead to the reduction of all sciences to one. A third reason is that, in most cases, the reduction of one theory to another is only partial, in that it requires the adjunction of premises not contained in the reducing or basic theory (Ch. 10, Section 3.1). Thus, to account for the very existence of a molecule we need not only quantum mechanics but also a set of subsidiary hypotheses; for example, the theory of the hydrogen molecule is not indebted to that of the hydrogen atom. (More in Vol. 6.)

In addition to the above conceptual obstacles to full reduction there is

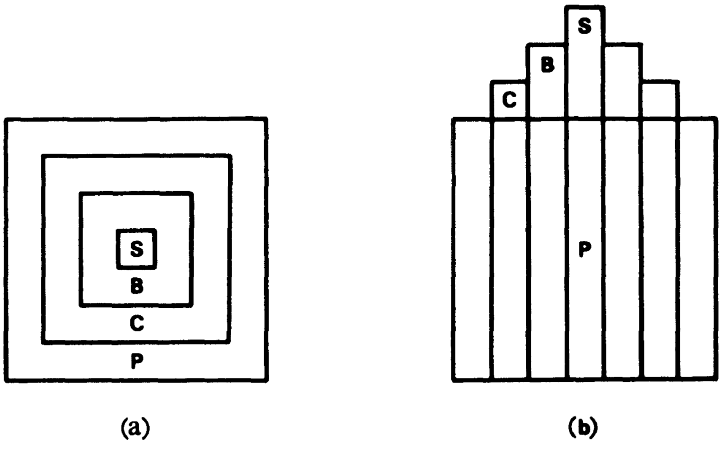

Fig. 13.3. (*a*) Ontological reductionism: reality is a system of Chinese boxes. Higher level things are just special cases of lower levels. (*b*) Ontological emergentism: reality is a telescopic system. Every higher level is composed of things that possess some emergent properties in addition to some of the properties characterizing lower level things. '*P*' stands for the collection of physical things, 'C' for chemosystems, 'B' for biosystems, and 'S' for sociosystems.

one of a practical nature, namely computational difficulty. Take for instance the problem of calculating *ab initio* the possible energy levels of the chromosome of *Escherichia coli*, the best known cell and a comparatively simple one. Since the chromosome consists of a double-stranded DNA molecule with a molecular weight of about 2,800,000,000, in order to account for every single interaction among its subatomic components we would have to set up and solve a wave equation with about 10^8 terms, a task beyond human capacity. It is therefore reasonable to give up such a reductionist attempt and analyze the molecule into manageable modules. In short, reduction cannot always be performed, be it for conceptual or for practical reasons.

Still, the unity of science is a worthy goal, and one that is being attained through both reduction and integration. Why is such unity desirable? First, because the world happens to be one even though immensely rich both quantitatively and qualitatively. This unity suggests that many of the barriers among the various research fields are the product of ignorance or accident, hence unjustified. Such barriers are in our brains not in the external world. Second and consequently, the *rapprochement* and eventual fusion of different fields of inquiry is bound to be fruitful if they study the same objects (the case of ethology and neuroscience) or if one of them studies the components of the systems investigated by the other (the case of psychology and sociology). By getting together with its neighbors, each research field illuminates and checks the other. (Recall the requirement of external consistency or coherence of every body of knowledge with its nearest neighbors: Ch. 12, Section 3.1.)

A fourth reason for wishing to attain or rather strengthen the unity of knowledge is from the limitations of specialization. The division of labor, though necessary to obtain accurate and deep knowledge, may reach a point when it becomes an obstacle to further progress. As Adam Smith noted two centuries ago, narrow specialization blocks technical innovation. The same holds for scientific research: the narrow specialist tends to lose sight of the scientific enterprise as a whole, to the point that he may become an eminent technician ignoring everything that goes on around him. As a result he does not enjoy the benefits of the flow of information and the suggestion of analogies from one field to another, and he is unlikely to be able to cope with new problems requiring an integrated approach. By specializing in excess he has fallen into routine, i.e. the very opposite of innovation. This is one reason that many a scientific, technological and humanistic revolution has been the work of marauders free from the fetters of disciplinary tradition. For example, physiological psychology was founded by two physicists, Helmholtz and Mach; and the Mach bands, which we now attribute to lateral inhibition, were intensively investigated by Békesy, originally a communications engineer. Molecular biology was largely the creation of physicists and chemists: Watson was the only biologist among the fathers of the new discipline. And operations research, or large scale management, resulted from the joint efforts of physicists, mathematicians and engineers—not of administrators or strategists.

We have begun to understand that the current fragmentation of science, technology and the humanities hinders their advancement: that breakthroughs in all fields of inquiry can be obtained only by a judicious combination of specialism with generalism. The model to be imitated is neither the assembly line worker nor the handy man, but instead the specialist with a general background and outlook, who keeps updating and diversifying his knowledge, who keeps abreast of advances in adjoining fields as well as tries his hand at some problems in them, perhaps to the point of changing professions once or twice in life. In short, the best expert is the generalist with specialized knowledge—or, if preferred, the specialist with general interests. It is people of this kind who contribute to creating new research fields or to merging different specialties, and in general help redraw interdisciplinary boundaries. It is also people of this kind whom we seek as our family's doctor: people able to take care of the whole, not by ignoring the findings of the various specialists but by integrating them. If this strategy works to keep us whole, why not use it more often to improve the health of our badly fragmented intellectual culture?

3. Evolution and revolution

3.1. *Paradigm*

Every human being is born into a culture, and every culture includes one or more fields of knowledge, some of which are rather closed belief systems (e.g. religions) whereas others are open research fields (Ch. 2, Section 4.1). Every one of these epistemic fields includes one or more conceptual frameworks. Each such conceptual framework is composed in turn by a general outlook or philosophy, a body of background knowledge, and an accepted thought style which includes certain methods for handling problems of a given type. In mature research fields a few such frameworks dominate at a given moment whereas the competing frameworks are marginal. The dominant conceptual frameworks, or *paragons*, have been variously called *thought styles* (Fleck, 1935) and *paradigms* (Kuhn, 1962). In developing research fields there are no such dominant conceptual frameworks, thought styles, or paradigms. Thus psychology and sociology are still in search of their paradigms, whereas chemistry has its own. (Contrary to widespread opinion, a mature science need not have a single paragon. Thus a chemist may use, in the same research, classical chemical kinetics, a spoke-and-ball model of molecules, and quantum chemistry—three paradigms altogether.)

Those of us who become professional inquirers—scientists, technologists, or humanists—do so by grasping the main features of the paragons in at least one research field, usually in two or more. We learn mostly by studying model cases or *exemplars* (Kuhn's apt term) of problem solving. And we make original contributions when posing or solving new problems within the existing framework, or when introducing some important and viable alterations in the latter. In the first case we conduct, to employ another of Kuhn's favorites, *normal* research. In the second case we engage in *extraordinary* research, which may result in an epistemic breakthrough or even revolution. All this has been known to scientists, technologists, and historians, for quite some time: Kuhn's (1962) modern classic had the merit of bringing it to the fore. What remain problematic are the very notions of a conceptual framework and of a paradigm, and of a revolution in it. Neither of these notions has been elucidated carefully, either by Kuhn or by his followers or critics. (See, e.g. Lakatos and Musgrave, 1970.) Let us apply our tools to clarify those notions.

In Ch. 2, Section 4.1 we characterized a field of inquiry as being formed by a material framework and a conceptual one. The former is constituted by an inquiring community (or rather a community of inquirers), the society supporting (or at least tolerating) it, and the sort of thing that the inquirers study. (In the case of the formal and humanistic disciplines the "things" being studied are conceptual objects, so the expression 'material framework' is somewhat misleading: a better name is wanted.) A *conceptual framework* in any given epistemic field $\mathscr{E}$ was characterized as a septuple $\mathscr{E}_c = \langle G, F, B, P, K, A, M \rangle$, where

G = *general outlook* or philosophical background,
F = *formal background* (logical or mathematical presuppositions),
B = *specific background* (body of borrowed knowledge),
P = *problematics* (collection of problems that may be investigated in $\mathscr{E}$),
K = *fund of knowledge* previously obtained by members of the inquiry community,
A = *objectives* or goals of the inquiry, and
M = *methodics* (collection of methods of $\mathscr{E}$).

Except for the occasional impostor, every member of a research community is engaged in designing or implementing one or more research projects. A *research project* in a research field characterized by a conceptual framework $\mathscr{E}_c = \langle G, F, B, P, K, A, M \rangle$ may be construed as a septuple $\rho = \langle g, f, b, p, k, a, m \rangle$, where every component is a subset of the corresponding component of $\mathscr{E}_c$. Two or more research projects are said to *compete* with one another it they deal with roughly the same problems in different ways, e.g. using different special methods. For example, at one time physicists were divided into corpuscularians and plenists (or continuists); and nowadays sociologists may be classed into holists, individualists, and systemists. There is no competition if the aims are different—e.g. theoretical in one case and practical in the other.

An *exemplar* may be defined as a research project that, (*a*) having proved successful in the past, (*b*) is imitated (taken for a model) for the conduct of further research work. Lakatos (1970) proposed his own notion of a *research programme*, conceived as a sequence of theories in themselves (i.e. dwelling in the platonic realm of ideas), as an "objective reconstruction" of Kuhn's notion of a paradigm. Actually it is an adulteration of it, because for Kuhn (*a*) research is not restricted to theorizing, and (*b*) theories do not hover above social circumstances. The thrust of Kuhn's view is that inquirers do not work in a social vacuum but in a research community. Much the same can be said of the analysis proposed by Stegmüller (1976)—which, moreover, rests on the analysis of theories due to Sneed (1979), criticized in Ch. 9, Section 1.2.

We define *normal research*, be it in science, technology, or the humanities, as the implementation of a research project within an existing conceptual framework and in imitation of some exemplar or paradigm. *Extraordinary research*, on the other hand, is that which may result in a radical innovation in some conceptual framework, such as a substantial change in general outlook, problematics, or methodics. If successful, the new conceptual framework generates new paradigms which inspire a new run of normal research.

Normal research is the bread and butter of investigators, and much of it is exciting. (Even those few revolutionaries who succeed in constructing a new conceptual framework do normal research when they adopt the new paradigm to investigate problems other than those that gave rise to the new framework.) Normal research is often predictable in outline but need not be always so. In fact it sometimes proves our intuitions and expectations wrong, as when Maxwell discovered that the viscosity of a gas is unrelated to its density. (For a good selection of surprises in the course of normal research in contemporary theoretical physics see Peierls (1979).) Moreover most breakthroughs are effected within existing conceptual frameworks. *Examples*: the 18th century work in mathematical analysis (in contrast with the invention of the latter in the previous century); Laplace's work on probability (*vs*. the earlier work); Frege's contribution to logic (*vs*. that of Boole and De Morgan); the axiomatization of set theory (*vs*. its creation by Cantor); modern solid state theory and quantum chemistry (*vs*. quantum mechanics); and even molecular genetics (*vs*. classical genetics) according to Maynard Smith (1972).

Extraordinary research involves a change in thought style and therefore it elicits a reorientation of research. If the outcome is a substantial advance, it constitutes an epistemic revolution—what Bachelard (1938) called a *rupture épistémologique*. Moreover, a successful research project will be said to be an *epistemic revolution*, relative to a given conceptual framework $\mathscr{E}_c$, if and only if (*a*) it involves radical departures in some (not all) of the components of $\mathscr{E}_c$, or (*b*) it opens up a whole new research field (without however cutting ties with all of the existing ones). Clear cases of epistemic revolutions were those effected by Newton, Darwin, Marx, and Cantor. They changed the prevailing modes of thinking in a deep and lasting way.

However, extraordinary research need not be revolutionary: it may ensue in an epistemic counter-revolution, i.e. a partial return to an earlier conceptual framework. (There are never total returns.) More precisely, a research project may be said to be an *epistemic counter-revolution*, relative to a given conceptual framework $\mathscr{E}_c$, if and only if it involves (*a*) giving up, for no good reasons, substantial portions of any of the seven components of $\mathscr{E}_c$, or (*b*) returning to ideas or procedures that had proved to be inadequate in the past and moreover were superseded by $\mathscr{E}_c$. Contemporary cognitivism, with its obsolete mentalism, its disregard for biology, and its lack of concern for experiment, is a rather clear case of counter-revolution; the romantic revolt against positivism (e.g. Feyerabend, 1975) is another. In still other cases extraordinary research results in a mixture of revolution and counter-revolution. An instance of such mixture is behaviorism, with its scrupulous methodics, narrow problematics, and almost total renunciation of theory. Another mixture of revolution and counter-revolution is transformational linguistics, with its formal rigor and exciting new problematics allied to traditional mentalistic psychology and scant concern for empirical test.

Some philosophers, notably Popper (1970), take normal research to be a matter of routine and even dogma, hence full of dangers. This is not so. As we saw a while ago important and surprising breakthroughs can be made within existing conceptual frameworks. Moreover, every epistemic revolution has its roots in some conceptual framework or other. What is true is that normal research is not as glamorous as extraordinary research, and therefore does not often come to the attention of philosophers. And it is also true that clinging to any given conceptual framework, no matter how fruitful it may have been, may end up in dogmatic rigidity: in the refusal to try new theories or proposals, and occasionally also in the refusal to admit defeat in the face of empirical evidence. This point deserves a new paragraph.

Kuhn's most important contributions to methodology are perhaps his ideas that in every science there is a permanent tension between tradition and change, and that negative evidence is treated differently by normal research and by extraordinary research (Kuhn, 1977). The former idea, though obvious, bears hammering, and anyway it is alien to both gradualists (who view the history of knowledge as cumulative) and catastrophists (who focus on revolutions and ignore normal research). The second idea is more original: it is that, whereas normal research attempts to *accommodate* negative evidence to the ruling conceptual framework, extraordinary research uses such anomalies to *undermine* the framework.

The accommodation of negative evidence to the ruling paradigm can be effected, in all honesty, by augmenting the traditional theory with *ad hoc* hypotheses designed to save it, or by proposing new theories conceived in the "spirit" of the prevailing conceptual framework. There is nothing wrong with any of these tactics unless serious anomalies keep cropping up, i.e. unless the prevailing conceptual framework enters in a crisis. In such case it is advisable to try radical alterations. Of course, any such reform projects will be resisted by researchers who have become attached to the old framework. They may become so conservative as to censor the publication of criticism, of new ideas, and even of unfavorable data. But eventually resistance to novelty weakens and the new framework prevails: change is of the essence of science and technology.

3.2. *Revolution*

Human knowledge can advance *gradually*, by *breakthroughs*, or by *revolutions*. Gradual advance consists in accretion or attrition: in gaining some items of information or in discarding others upon being recognized as inadequate. Gradual advance occurs always within some conceptual framework or other. Once in a while a breakthrough occurs within a conceptual framework, namely when an important problem or problem system is solved, so that new problems can be posed within the same framework. And revolutions consist in the emergence of new conceptual frameworks, which replace either old ones or just plain ignorance.

This being so, it is a mistake to opt for either gradualism (favored by empiricism) or catastrophism (favored by both rationalism and irrationalism). The history of knowledge, like that of every other human endeavor and, indeed, any other sector of reality, exhibits not only gradual changes and breakthroughs but also revolutions. The synthesis of gradualism and catastrophism is *evolutionism*. According to this view there is (*a*) *permanence* of some over-arching philosophical principles that propel all objective inquiry (e.g. the theses that reality is lawful and can be known), (*b*) *ceaseless addition and deletion* of data, techniques, hypotheses, and

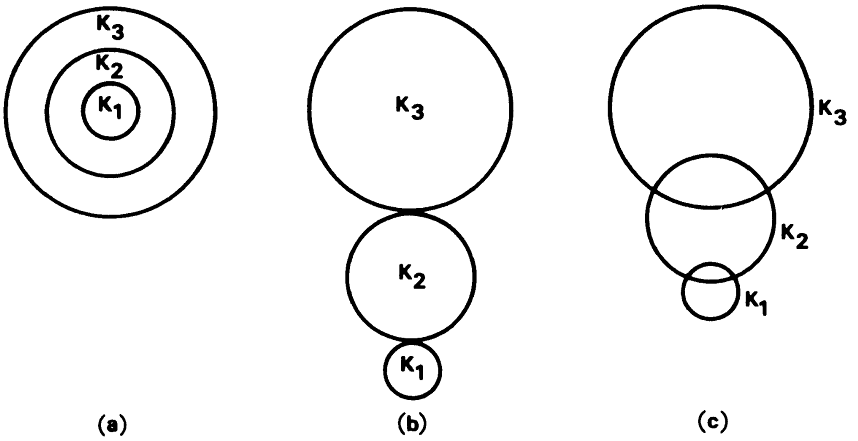

Fig. 13.4. Three models of the evolution of knowledge. (*a*) *Growth*: successive bodies of knowledge include the previous ones. (*b*) *Revolution*: successive bodies of knowledge are mutually incommensurable. (*c*) *Evolution*: successive bodies of knowledge overlap partially.

theories, and (*c*) *occasional revolutions*, using some background knowledge and upsetting other components of it, that result in new conceptual frameworks. See Figure 13.4.

The evolutionary view of the march of knowledge keeps the sound theses of both gradualism and catastrophism while rejecting the false or misleading ones. In particular, evolutionism rejects the fashionable thesis that knowledge advances primarily by replacement, not by addition. This is not always so: mathematical analysis, abstract algebra, genetics, control theory, psychobiology, and economic history—to cite but six scientific revolutions—replaced nothing but ignorance. In these and many other cases there was no rival conceptual framework to be criticized and replaced.

A second, related thesis, is that every epistemic revolution is a response to some crisis. (A research field is said to be in a state of *crisis* if it is stagnant, or is dominated by a single narrow school, or is fragmented into several warrying schools, or is split into many narrow and weakly related specialties, or some of its own accomplishments are threatening its dominant conceptual framework.) True, every epistemic field seems to have passed through a period of crisis, and some fields, such as sociology, seem to be in a permanent state of crisis. However, in some fields breakthroughs and even revolutions may occur without any deep crises. For example the discovery of inconsistencies in mathematical analysis, and later on in set theory, did not throw the mathematical profession into disarray and did not force it to give up any basic principles. The problems were solved with more of the same, i.e. more rigor and further theories.

A third mistaken thesis of catastrophism is that every epistemic revolution razes past accomplishments: that it produces the "collapse" of earlier theories and methods, which are "overthrown" by the victorious rivals. This analogy with politics and warfare is wrong in many cases. Thus Einstein's two relativities, far from demolishing classical physics, constituted its apex: Einstein continued and culminated the work begun by Faraday and Maxwell, as well as by Poisson and Riemann. Furthermore, the news of the demise of classical mechanics and other classical theories is exaggerated, as Mark Twain would say: they are still being worked out and modernized by physicists and mathematicians, and used by engineers. After all, in many cases they help solve problems to an excellent approximation. And in any event even the most drastic revolutions are partial: they alter only some components of the total system of knowledge at any given time.

A fourth mistaken thesis of catastrophism, and a most dangerous one, is that rival frameworks are "incommensurable"—by which "incomparable" seems to be meant, though this is not certain, for romantics are characteristically sloppy. In particular, rival scientific theories would not have a common core of meaning: their senses and reference classes would be entirely disjoint. We have criticized this view in Vol. 1, Ch. 2, Sections 4.2 and 5.1, and Vol. 2, Ch. 7, Section 3.3. Suffice it to note here that, if two theories are deemed to be rival, it is because they share referents and even allow one to pose some common problems. Thus the theory that some mutations are neutral competes with standard genetics, according to which every mutation is either advantageous or, more often, disadvantageous. On the other hand no linguistic theory could possible rival a geological one, for they deal with different domains. In any event it is common practice to compare rival theories and methods, and to choose between them with the help of more or less explicit criteria (Ch. 12). To assert that the choice must be irrational is to distort the picture of actual research and to make an unnecessary concession to irrationalism.

Finally, a fifth and equally dangerous thesis of catastrophism is that each conceptual framework is a sort of mental prison out of which we cannot escape in any rational way: if we do escape it is by an act of faith. Surely this thesis is psychologically and methodologically wrong: scientists and technologists do not operate like mystics or like blind followers of a political ideology, but are often capable of examining their pet theories and methods with a critical eye. They can admit formal or empirical defects and can do something about them, at least tolerate attempts to solve the difficulty. As Popper (1970, p. 56) wrote, "if we try, we can break out of our framework at any time".

In sum, the march of knowledge is smooth in some respects and discontinuous in others. All change, even the most drastic, is partial, not total. (Only crackpots reject the totality of the existing system of knowledge.) And epistemic changes are uneven: at each period some branches of knwledge advance faster than others, thus providing inspiration or even leadership to the less developed ones. Moreover the advancing edge does not fill all the gaps in knowledge: countless pockets of unsolved problems remain behind, some of which are taken up later whereas others are forgotten.

Some of the crucial advances in knowledge have been both philosophical and scientific. In particular, some have consisted in *epistemological revolutions*, or radical changes in the way of gaining knowledge. One of them was introduced by the Ionian philosophers of nature, in particular the atomists: it consisted in replacing myth (in particular religious myth) with naturalistic speculation consistent with (though not suggested by) observation. Another was Archimedes', namely the combination of mathematics with observation and measurement (and possibly also with some experiment) to produce the first mathematical models of things, namely statics and hydrostatics. This process was quickly halted but was resumed sixteen centuries later by Galileo. He replaced the reading of the Scriptures with the "reading the book of Nature" with the help of mathematics, measurement, and experiment. A fourth epistemological revolution was brought about by Newton, who created the first general, exact, and nearly true factual theory in history, and showed how to use mathematics to build theories and formulate problems. A fifth epistemological revolution accompanied the Industrial Revolution and is still going on: it was the birth of science-based technology.

A sixth epistemological revolution started nearly two centuries ago: it consists in studying human nature and human society the same way nature is studied, namely by observation, measurement, experiment, and mathematical modeling. A seventh epistemological revolution was the invention of the theory of evolution by natural selection: from Darwin on not only organisms but also ecosystems, societies, institutions and even molecules are "seen in an evolutionary perspective", i.e. as members of evolutionary trees and as the results of variation and selection. An eighth epistemological revolution is the computer revolution, which makes it possible, among other things, to solve computation problems that are far beyond the reach of the individual brain assisted only by paper and pencil. Finally, an ongoing epistemological revolution is that introduced by physiological psychology, according to which cognition is not an operation of an immaterial mind but a brain process. All these epistemological revolutions shattered long-established traditions, such as those of relying on myth, or on observation unaccompanied by testable theory, or on routine techniques handed down by the craftsman to his apprentice. However, in every case some regulating principles and some bodies of knowledge were preserved. Even the boldest of explorers needs some equipment, although he may have to alter or discard some of it in the course of his travels.

Sometimes three other events are cited as epistemological revolutions: the practice of systematic observation at the beginning of the Modern period, the requirement of operational definitions, and the introduction of considerations on the observer in the quantum theory. Actually neither of these was an epistemological revolution. Man has always observed, and many people have made extensive, meticulous and systematic observations before—though with little result because of lack of good guiding hypotheses. The novelty introduced by the 17th century in this respect was the use of observation (and measurement and experiment) to *check* hypotheses. As for operationism, or the requirement to "define" every concept in terms of instrumental operations, Bridgman (1927, p. 2) regarded it as a guarantee *against* any further revolutions. He thought that we would stop drifting if only we were to anchor every concept to the supposedly solid rock of laboratory operations. Finally, although Bohr, Heisenberg and others did think that they were producing a revolution by invoking the subject every time they interpreted a quantum-theoretical formula in terms of observations, actually they retreated from the ideal of objectivity, so the Copenhagen interpretation they built was *counter*-revolutionary. Fortunately it can be shown (Bunge, 1967c, 1973a) that such interpretation is groundless, for it matches neither the mathematical formalism of the theory nor the actual practice of physicists.

Finally, note that many a revolution in knowledge has been the product neither of new empirical evidence nor of rational criticism. For example, demonology was not discredited by new, adverse empirical evidence, for every bit of experience could be absorbed or "rationalized" by demonology itself. Nor was it discredited by the criticism practised by a few bold and enlightened humanists and theologians, for they had nothing positive to offer instead of a body of belief that could encompass such wide experience.

As Trevor-Roper (1967) has shown, demonology died together with the whole medieval world view, which fell when the new positive philosophy of nature proved more powerful than the old one: it was one of the casualties of the triumph of the new mechanical world view built by Descartes, Galileo, and a few others. Moral: Don't neglect world views, particularly since a theory or practice that is upheld by the prevalent world view is nearly unassailable, whereas one that lacks such support is unlikely to succeed.

4. Limits and prospects

4.1. *Limits to Inquiry*

Are there any limits to what we may know? Barring the skeptical answer—that we can know nothing—three replies to that question have been given. One is optimistic: there are no bounds on inquiry. Another is pessimistic: there are severe limitations on what we can know, and we may already have reached the end of our tether. The third is realistic: there are limitations, yet boundless progress is possible, though not inevitable.

The optimistic thesis is that of the Enlightenment. (See, e.g. the reception speech of the marquis de Condorcet at the French Academy in 1782.) This thesis is little more than an article of faith suggested by the scientific, technological and humanistic progress since about 1600 in Western Europe. The pessimistic thesis is based on certain beliefs on the human mind and society. One of them is that the human mind is a finite capacity information processor composed of a large but finite number of finite elements, so that sooner or later it will exhaust all their possible combinations. Another is nativism, according to which we never learn anything, all our ideas being innate. A third belief is phenomenalism, or the thesis that we can know only appearances and the relations among them, never reality, let alone any essential properties of it. A fourth belief is that every society, and perhaps even the whole of mankind, is bound to decline, for having exhausted its drive, or for being unable to surmount its inner conflicts, or for having degraded its natural resources.

The optimistic thesis ignores the real constraints on inquiry, such as the upper bound on the velocity of propagation of all signals, whereas the pessimistic thesis exaggerates them. The former does not account for any setbacks, such as those of the Counter Reformation, Nazism, Stalinism, and the current restrictions on research budgets in the USA and elsewhere.

As for the pessimistic thesis, recall the fate of all the gloomy prophecies on the future of inquiry. On the eve of the relativistic and atomic revolutions Lord Kelvin prophesied that the next advances in physics would only add a few decimal figures to the value of the physical constants. (For more recent pronouncements on the near completion of knowledge see Schlegel (1967) and Stent (1978).) At the end of the first World War Oswald Spengler wrote the obituary of the so-called Western civilization, and two decades later Cristopher Cauldwell that of "bourgeois" culture. Both prophecies were followed by unprecedented advances in all fields of research. Better refrain from making prophecies and contribute instead to the pursuit of knowledge.

Given the failure of both the optimistic and the pessimistic theses, let us turn to the realistic one. (For details see Bunge (1978a).) There can be no doubt that the pursuit of knowledge is subject to constraints of various kinds: physical, biological, and social. The former consist in the impossibility, be it in principle or in practice, of obtaining certain informations, e.g. about the documents contained in the archives burned during the Thirty Years War. The biological constraints on our cognitive activities boil down to this: we cannot outfox our own brains—and human brains, though marvelously competent, presumably are not the last evolutionary word. And the social limitations on inquiry stem from the economic, political and cultural matrices of every scientific community. The social pressures on a community of inquirers may become so intense that research may stagnate, decay, or even disappear altogether at least for a while. Such social constraints have nothing to do with the physical or biological ones, hence they can be relaxed. Let us take a closer look at the three types of constraint.

The *physical limits* on inquiry consist essentially in that not every desirable item of information is accessible. There are at least two classes of events of this kind: those about which all information has been lost, and events about which any information will be too late. A clear case of lost information is this: if the "big bang" cosmological theory is true, then the history of the universe before the beginning of the expansion has left hardly any traces, so we cannot possibly learn anything about that segment of eternity. A similar case, on a far more modest scale, is the loss of geophysical—in particular geological—information as a result of physical processes such as the melting of rocks. The destruction of prehistorical evidence and historical records is similar. However, we may take heart on recalling that we keep discovering or inventing new ways of finding and interpreting traces of past events. So, the historical record, though hopelessly incomplete, can be reconstructed in part with some imagination.

In other cases there are events but there is no information to be had about them. For example, we cannot know what is happening right now in some remote corner of our galaxy, let alone in other galaxies. If and when the light signals accompanying some such events reach the present abode of mankind, they will give only a partial picture and one that may find no beholders. (In other words, the events about which you can get information are those lying within your own light cone.) However, what a single observer cannot attain, a few generations of observers, bound by a common scientific tradition, may attain: some of the signals that are now leaving more remote places will reach some of our descendants, so they may be able to know what is going on out there.

As for the future, it may be conjectured with the help of laws and a knowledge of present circumstances. Surely some of our predictions are probabilistic, but this is no limitation if the processes themselves are stochastic, as is the case with atomic, genetic, and social processes. For example, although we cannot predict when a particular radioactive atom will decay, we can predict when the radioactivity of a large aggregate of atoms of a certain kind will be halved.

In sum, scientific inquiry is subject to certain physical constraints. These constraints limit the amount of information that can be won, but they need not slow down the pace of scientific progress. We can know more and more about certain things while ignoring everything about others. We need not worry about all we shall never know provided we keep on finding out some of the infinitely many things that can be known.

Let us now turn to the *biological constraints* on inquiry. Ours is the most plastic of all known brains, and so the one capable of learning the most. As society becomes more complex and culture richer, our brains are subjected to an increasing amount and variety of stimuli, which elicit an ever increasing number and variety of synaptic connections. The development of a child's brain is probably far swifter nowadays than it was one century ago. And our readiness to expect novelty and to seek it is certainly greater than that of our ancestors, most of whom resisted novelty. Surely there is more to be learned today, but we do not have to learn everything our ancestors knew. We can learn to pilot airplanes without first having to learn to drive oxcarts. The same holds for science and technology learning: most of the theories and data a student is supposed to learn are comparatively new. Progress makes up for the limited human life span.

Much more serious a limitation on the human cognitive ability would seem to be our limited channel and storage capacity—to say it in computerese. But these are not really disadvantages: if we were capable of admitting all stimuli, we would be unable to concentrate; and if we were capable of recalling every single experience we would hardly be able to conceive of new ideas. Blessed be our sensory inhibitions and memory limitations, for they allow us better to create.

Anyway, the brain-computer analogy is superficial. Human brains are biosystems not artifacts: they develop and, collectively, they evolve. Moreover, unlike other organs, the human associative cortex is highly plastic: it does not deliver the same outputs every time it is presented with the same inputs, and it is in permanent activity. Furthermore it is possible that the various mental functions are performed not by fixed neuronal systems but by itinerant ones formed afresh every time a new task arises (Bindra, 1976). If this is so, even though the number of neurons is finite, that of neuronal systems capable of performing mental functions is practically infinite.

The real limitation of the human brain lies elsewhere and it is not to be found out by comparison with computers. It derives from the inability of our associative cortex to function properly unless it is connected to the brain stem, the hypothalamus, the endocrine system, the peripheral sensors, and, indeed, the whole rest of the body. It is these extracortical systems that keep the associative cortex awake and active—and which at the same time cause the nonrational streaks of human thought. We cannot think unless we are alert and motivated, but if we are alert we cannot avoid some distraction; and if we are motivated we cannot keep totally cool. In sum, pure reason is biologically impossible.

However, we often do manage to think rationally and to make rational decisions, and this because we are not isolated. Sensory deprivation leads to hallucination, and social deprivation to mystical visions. I cannot think rationally all the time, nor can my partner, let alone my rival; but they correct me when I lapse, and all three together manage to set up—unwittingly to be sure—a self-correcting system within which we can be sane and productive, outside of which insane or barren. Human knowledge, particularly of the scientific or technological kind, is produced by individuals in society, and ought therefore to be always public property.

In short, the biological constraints on cognition, though real, are less formidable than they appear at first blush. First, because the human brain is marvelously plastic and capable of spinning out new ideas without end.

Second, because the scientist, technologist or humanist need not, nay must not, rely exclusively on himself. He counts on all his peers, this being why he writes *we* know where the artist writes *I* know. His personal limitations can be overcome by learning from the dead and cooperating with the living. He works, in short, in an inquiring community held together by an information network. (Recall Ch. 3.) Which brings us to the third and last type of constraint on inquiry.

Every inquiring community is a subsystem of some culture or other, which in turn is a subsystem of some society, in turn a component of the international system. The culture of a society is only one of its three artificial subsystems, the other two being its economy and its polity. Each of these subsystems interacts strongly with the other two. (cf. Vol. 4, Ch. 5.) In particular culture—and so science, technology, and the humanities—is subject to intense economic and political pressures. So, far from being autonomous, science, technology and the humanities thrive or wither along with society.

A peasant economy cannot support a space research program; a totalitarian state does not tolerate free inquiry into political problems; and a religion-oriented culture does not encourage studies on the origin of life, biological evolution, the physiology of thinking, or the socioeconomic roots of religion. It does not follow that an industrialized society, with a democratic polity and a lay culture, will necessarily support scientific and humanistic research. It will, provided the prevailing ideology happens to be favorable to inquiry—otherwise not. Nor does it follow that an underdeveloped economy, allied to an authoritarian polity and a backward culture, will necessarily ban all inquiry. It may support some research, sometimes even at great sacrifice, as long as its ideology is friendly towards learning, or for believing mistakenly that basic research delivers technology. In sum, if we wish to understand the social control mechanisms of inquiry we must reckon with ideology, for ideology shapes public opinion, which in turn determines cultural policies, which regulate the only two contributions a society can make to its inquiring communities, namely human and material resources. (Tradition can be borrowed up to a point.)

Science and technology are so much taken for granted nowadays that we tend to forget how new they are and how exceptional were the circumstances of their emergence. Thus it cannot be a coincidence that science and mathematics, as well as philosophy, were invented in Greece during the 5th century B.C. Other civilizations had been more advanced in other respects and they shared a number of basic social and economic traits with the Greek city states, among them slavery. The one trait they did not share was political democracy, which was genuine as far as the Greek citizens were concerned. And political democracy involved civil rights, among them the rights to inquire, question, dissent and argue about everything except religion. Apparently nothing more than this freedom and some leisure was needed for mathematics, science and philosophy to flourish, as inquiry comes spontaneously to man, and social conditions can only stimulate or inhibit it. Technology is another matter: it also requires an industry capable of using it, and this was nonexistent in Antiquity. So, technology proper, i.e. technical knowledge based on science, could not emerge until the mid-seventeenth century. Since then science, technology and industry have been supporting one another, constituting a unique system unknown in previous times. We shall come back to this in Ch. 14, Sections 2.2 and 3.1.

To sum up, although there are physical and biological limits to what men can know, they need not impede scientific, technological or humanistic progress. The collection of knowable facts is a nondenumerable subset of the total set of facts, and there is no limit on the variety of plastic neuronal systems capable of handling those facts. The really important constraints upon the evolution of science, technology, and the humanities, are social—economic, political, and ideological. Hence the importance, for all inquiring communities, of a sociology and politology of knowledge capable of revealing the external stimuli and inhibitions to inquiry. We shall return to this point in Ch. 15.

4.2. *Prospects of Inquiry*

What are the prospects of inquiry in science, technology, and the humanities inspired in science? That is, what is the future of our science-oriented culture? Let us not ask *what* discoveries and inventions will be made, for to do so would be to indulge in fiction—except of course in the relatively uninteresting cases where the outcome of current research is predictable. Let us ask instead the far more radical, important, and topical question *whether* research will be conducted at all in the near future.

Most people seem to be optimistic about the prospects of inquiry, and they offer the following reasons for such attitude. One is that modern civilization needs science, technology, and even the humanities. Indeed, there is no technological advance without research, and much of technological research is indebted to science. It is a question not just of continuing to borrow from past achievements, for many of them become obsolete and also because technology and the economy are constantly running up against new problems calling for new theories, methods, and data. So, if modern civilization—i.e. industrial society in any of its versions—is to go on, research must go ahead. This is the *argument from the practical value* of science. It is persuasive provided one accepts the antecedent, i.e. the thesis that industrial society is worth preserving—not so otherwise.

A second reason given is this. Modern society is becoming increasingly a service society: it needs physicians and dentists, veterinarians and agronomists, electricians and electronics experts, accountants and programmers, and so on and so forth, in increasing numbers relative to workmen and farmers. And those technicians cannot be properly trained, or contribute to the improvement of their techniques, unless they master the fundamentals of science. This is the *argument from services*, which is really complementary to the previous argument. Again, it holds water provided one cares for the service society.

A third argument is that science and technology have become no less than the left and right cerebral hemispheres of modern culture. They are intrinsically valuable in addition to having a practical value. Our schools teach them, and the public demands scientific and technological literature as well as gadgets. This is the *argument from the cultural value* of technology. It is correct but it has little practical value, for it will not persuade anyone who is mainly interested in fast profit or power. Besides, science and technology, unlike their industrial outputs, are still elitist. Only a very small fraction of the total population is ever given the opportunity of experiencing the thrill of discovery or invention. Most of us, even most philosophers of science and technology, have never done any research in either science or technology, and so have as much experience of them as the deaf have of music or the blind of painting. Worse, the antiscientific and pseudoscientific publications have a far wider readership than the scientific and parascientific ones.

Finally there is the *argument from politics*, according to which scientists, technologists, and their numerous auxiliaries—technicians, librarians, etc.—have become a substantial sector of modern society, so their needs and aspirations can no longer be safely ignored by the politicians. This argument carries little weight because most scientists and technologists are politically naive and passive: they have no powerful lobby in any congress.

All four arguments come down to this: Modern civilization, West and East, involves science and technology; hence, if it is to continue, science and technology have got to have a future. Unassailable. But who assures us that modern civilization will continue? There is no guarantee: no law of continuity, let alone progress. On the contrary, there are many disturbing signs of decline. Let us review them quickly.

A handful of recent events has badly shaken our faith in progress, particularly in the continued march forward of knowledge. One is the accelerated pace of the arms race, which employs roughly half of the best engineers of the world, wastes nearly two thousand million dollars per day, and is likely to end up in the ultimate democracy of ashes. The second is the rapid depletion of non-renewable natural resources amidst the nearly total indifference of most governments. The third is the near-sighted science and humanities policy adopted by a number of governments, that have shifted the bulk of public support from basic to applied science and technology. The fourth is the spread of religious fundamentalism and authoritarian ideologies, their attack on basic scientific theories such as the theory of evolution, and their attempt to restrict the right to know. The fifth is the revolt against reason, and in particular against science and technology, that is spreading among well-intentioned but ignorant young people who, mistakenly, see in inquiry an enemy of the people.

For all of these reasons we should not take science and technology for granted. Instead, we should ponder seriously the initial question, which might not have been asked in 1780, 1880, or 1980: Do science and technology, and indeed modern civilization, have a future at all? It is not that science and technology are in the grips of a conceptual or methodological crisis. On the contrary, the prospects for further sensational (big and unexpected) breakthroughs in every field of research are brighter than ever. But science and technology are the work of human beings who need a favorable environment. If such an environment is not provided, the coming generations, if any, may lose interest in science and technology. If this happens our offspring are in for a new Dark Age. We may already have entered a period of scientific and technological decline. The decline, if there is one, may be temporary or terminal. It is up to us which it is to be. There are no iron or even tin laws of scientific and technological development. Science and technology will become what scientists, technologists and their fellow human beings choose.

5. CONCLUDING REMARKS

Knowledge cannot be stored permanently, either in books or in a spiritual world, because it ages. Sooner or later every bit of knowledge becomes stale or, if still valuable, it is bound to be incorporated into new bodies of knowledge, where it acquires a new value. Research takes care of such epistemic metabolism.

Knowledge may pass away, inquiry need not—that is, provided there is the will to find out. Science, technology and the modern humanities are characterized not so much by the amount of knowledge they have amassed, as by their research pace. A swift pace, more than any other characteristic, is what separates them from other forms of knowledge.

Knowledge evolves both gradually and by fits. It evolves as research of all kinds—mathematical, experimental, historical, etc.—yields new results. Some of the results of research fill a predesigned mold—conceptual framework—whereas others break it. In either case good reasons are given for any departure from tradition. And no such departure is a total break with the past: there is discontinuity in some respects but continuity in others.

In principle the progress of knowledge is boundless, but in practice there are restrictions. For example, in principle every single fossil in North America could be dug out; but such digging on a continental scale is practically impossible. In general, there is a gap between what can be known in principle and what can be known in practice.

It is likely that what remains to be known is infinitely greater than what we already know. Yet we do possess already infinite knowledge of sorts. Thus we know how to construct infinite sets, such as continuous functions, and we know law statements that cover infinitely many states, such as the formulas for the propagation of a wave and for the energy levels of an atom.

The enthusiasts as well as the enemies of research and development tend to believe that science and technology cannot be stopped: that, once launched, they are bound to move forward. Taken literally this belief is absurd, for it is inquirers who discover and invent, compute and design, criticize and evaluate—and researchers may cease to exist either for lack of motivation or as a result of a nuclear holocaust. After all, inquiry has declined dramatically several times before and seems to be declining right now: there is nothing necessary about the progress of knowledge. What is true is that creative scientists and technologists, as well as humanists, are mainly inner-directed: they cannot help posing problems, making observations, framing hypotheses, or drawing blueprints—that is, provided they are tolerated by society. And this is precisely the point: society, or rather its rulers, may not cherish research, at least of certain kinds, for regarding it as dispensable luxury or as subversive.

In sum, mutability is one of the trademarks of scientific and technological knowledge. But it is not the only one, and in any case there must be differences between science and technology. Let us investigate them.

CHAPTER 14

KINDS OF KNOWLEDGE

What kinds of knowledge are there, what characterizes every one of them, and how are they related? These are some of the problems to be investigated in the present chapter. They are not very old: they were born with secular thinking, which in the West usually dates back to the Ionian philosophers of nature, and they were not investigated vigorously until the Renaissance. Thus the distinction between mathematics and the other sciences is attributed to Leibniz, and that between philosophy and the sciences to Kant. And the distinction among the various sciences was not drawn until the beginning of the 19th century, when the first modern universities were organized.

It is common to distinguish the following ten knowledge genera: ordinary knowledge, technical prescientific knowledge (technics), basic (formal and factual) science, applied science, technology, the humanities, the arts, ideologies, religions, and pseudoscience. However, the criteria for such distinctions are seldom explicit and clear. Nor is there consensus about such criteria. Thus according to some, the fields of knowledge differ by their subject matter; to others, by their method; to still others, by the kind of service they render to society; and to some, by the way their workers are trained and communicate among themselves. Finally, some scholars hold that such distinctions are conventional—human knowledge being in one piece—or pointless, human knowledge being non-existing.

We shall propose explicit definitions of the genera of specialized knowledge. However, we shall also note their interrelations for, in one sense, human knowledge is in one piece. The interrelations are of two kinds: systematic and heuristic. Two fields of knowledge can 'be said to be *systematically* related to one another if at least one of them borrows some knowledge from the other. Thus biology and chemistry are systematically related to each other, and so are economics and mathematics. And two fields of knowledge will be said to be *heuristically* related to one another if work in one of them is helped or hindered by the other. Thus religion discourages scientific inquiry, particularly into its own dogmas, but it may occasionally help some investigators conceive fruitful speculations concerning unobservable entities or properties. (However, religion is primarily a matter of faith not knowledge, so it is not really a field of knowledge.)

Since every field of knowledge is related both systematically and heuristically to some other field, one can rightfully speak of the unity of human knowledge amidst its amazing diversity. In fact we shall speak of the *system* of human knowledge—both as a system of knowing subjects and as a conceptual system. Moreover, since the production of knowledge is intimately related to the production, use and exchange of other artifacts, we may also speak of the *total system* of production and exchange of goods and services of all kinds, from theories, blueprints and works of art to cultivars, machines and educational services.

1. FIELDS OF KNOWLEDGE

1.1. *Knowledge Genera*

There are many ways of classing items, in particular bits of knowledge: as many as criteria (or equivalence relations) are adopted. (See Ch. 9, Section 1.1.) Indeed one may divide knowledge into genuine and bogus, theoretical and practical, scientific and nonscientific, factual and nonfactual, and so on. Which classing is the most convenient depends upon our goal.
